Abstract

We present a theoretical investigation of the effects of substitution of the triphenylamine (TPA) block on the overall properties of materials based on small push-pull molecules designed as donor for organic photovoltaics (OPV). In particular, we exploit modern computational techniques such as Density Functional Theory (DFT), Time-Dependent-DFT (TD-DFT), Molecular Dynamics (MD), and the Marcus theory,

to analyze the charge and exciton transport properties in crystalline and amorphous phases of four compounds in which one phenyl ring of the TPA block of 2-((5-(4-(methyl(phenyl)amino)phenyl)thiophen-2-yl)methylene)malononitrile is replaced by a methyl, a α-napthyl, and a β-napthyl. Our calculations unveil the molecular rationale behind the different transport properties observed in the experiments. We show that, although the effects of the substituents on the electronic and optical properties are negligible, they impact on the molecular packing of the crystalline structure, thus explaining the different macroscopic transport properties (observed and calculated). In particular, the substitution of a phenyl with a methyl favors face-to-face $\pi - \pi$ packing in the crystal structure and allows a good π-orbital overlap and high hopping rates. On the contrary, the introduction of an α-naphtyl group generates a steric hindrance that negatively affects the transport properties. Moreover, the investigated substitutions do not significantly influence the degree of local order in the amorphous bulks displaying complete disorder and low hole mobilities. These results, in agreement with the experimental findings, suggest that our computational approach is able to account for the macroscopic effect of subtle transformations of a molecular structure on transport properties and thus can be further employed to obtain valuable insights for the molecular design of optimized active materials for OPV.

Keywords

organic solar cells, HTM, DFT, MD, Marcus Theory

Introduction

Organic photovoltaics (OPV) is attracting increasing interest as an alternative to inorganic solar cells due to possible applications in low-cost, low environmental impact, light-weight and large-area flexible devices.[1–4] An organic solar cell (OSC) basically consists of the heterojunction created by contacting an electron donor material (D) with an electron-acceptor

(A).[5] The basic functioning of an OSC consists in four steps: the absorption of an incident photon by the active material (D in general) generates a bound electron-hole pair (exciton) which diffuses in the D phase and dissociates at the D/A interface. The resulting electrons and holes migrate in the D and A layers to be finally collected at the electrodes.[1,2]

The performance of an OSC depends on the efficiency of these four steps that is affected, in turn, by the properties of the materials employed in its fabrication. Its optimal performance requires an improvement of the characteristics of each constituents.[6]

OSCs can be roughly dived into two main categories. Bi-layer planar heterojunctions (PHJ) essentially fabricated by vacuum-deposition techniques[7,8] and bulk heterojunction solar cells (BHJ) in which the heterojunction created at the interface of segregated phases of donor and acceptor materials is distributed in the entire volume of a solution-processed active film. Besides fabrication by solution processes at room temperature, BHJs present the advantage of a large increase of the area of the D/A interface and thus to a better efficiency.[9,10] Whereas soluble conjugated polymers have represented the major class of donor materials for solution-processed BHJs for more than twenty years,[11] molecular donors have recently emerged on the forefront of research on the chemistry of OPV materials due to the advantages of well-defined chemical structures in terms of reproducibility of synthesis and purification and possible analyses of structure-properties relationships.[12–16] Thanks to a multidisciplinary research effort focused on both the optimization of cell fabrication and the synthesis of new donor materials, conversion efficiencies comparable to those obtained with the best polymer-based cells ($> 10\%$) have been recently reported for BHJ cells based on molecular donors of relatively complex chemical structure.[17] Besides high conversion efficiency, a future industrial development of OPV depends on the possibility to offer decisive economic and environmental advantages over existing technologies. In this context, the development of active materials combining simple, cost-effective, clean and scalable synthesis represents a key issue for the chemistry of OPV materials.[18]

In this work we focus on the donor materials. In particular, an efficient donor material for

OPV must combine:[19] (1) good light-harvesting properties namely an absorption spectrum covering a large part of the solar irradiation spectrum and a high molecular extinction coefficient; (2) high hole mobility and exciton diffusion coefficient in order to minimize the transport resistance in the bulk; (3) large delocalization of the highest occupied molecular orbital (HOMO) that facilitates hole transport; (4) low HOMO energy level that increases the open circuit voltage (V_{oc}) of the solar cell; and (5) a high exciton diffusion coefficient and low exciton binding energy facilitating the exciton dissociation at the donor-acceptor interface.

A typical strategy employed to propose novel and more performing molecules consists in optimizing a reference skeleton with substituent groups that would enhance its charge and exciton transport properties.[20–22] The structural change of the molecular scaffold is aimed at optimizing the relevant photovoltaic parameters of solar cells adopting these donor materials.

Recently, small triarylamines-based (TAA) donor molecules have shown interesting photovoltaic performances.[14,16,23,24] The number of TAA-based molecules studied within this context is huge, thus showing the fervent experimental interest on this subject.[25–27] Owing to a combination of electron-donor properties and high hole-mobility TAA represent a major class of key building blocks for the design of metal-free chromophores for dye-sensitized solar cells[28,29] and donor materials for OPV.[12–16,21,30–32] Much work has already been devoted to the analysis of structure-properties relationships in TAA-based molecular donors for OPV and in particular, recent results on push-pull systems have shown that replacement of a phenyl groups of the triphenylamines (TPA) block by some aromatic or aliphatic substituents has negligible impact on the electronic properties of the molecule but can induce dramatic changes in the charge-transport properties of the resulting materials. In particular, replacing an outer phenyl group of compound 2-((5-(4-(methyl(phenyl)amino)phenyl)thiophen-2-yl)methylene)malononitrile (**1**)[33] by a methyl group (**1-Me**) or the α-naphtyl group of **2a** by a β-naphtyl (**2b**) (Figure 1) leads to a significant increase of hole-mobility and photovoltaic conversion efficiency.[32,34]

In this context computational techniques represent a powerful tool that allows to understand, at the atomistic scale, the physical phenomena that lie behind the transport properties unveiling the structure-property relationship in this class of molecules.[22,35,36]

Theoretical studies based on classical Molecular Dynamics (MD) and quantum chemical calculations were recently employed to fully characterize the structural, electronic, optical, and transport properties of organic semiconductors in solar cells.[35–41] Charge and exciton transport in organic semiconductors is commonly described as a hopping process whose rate can be derived from the Marcus theory.[42] This technique can be successfully used to calculate the charge mobility, or the exciton diffusion coefficient, employing a master equation or the Kinetic Monte Carlo (KMC) approach.[43,44] The quantities entering the Marcus rates can be calculated using the most appropriate level of theory depending on the complexity of the studied system. In this context, it has been showed that Marcus rates calculations based on the use of a semi-empirical Hamiltonian (ZINDO) produce reliable results that can be compared to the experimental values. This technique is thus suitable to study transport on large scales or complex systems.[45,46] Not surprisingly this approach was successfully applied to the study of hole transport in molecular and polymeric systems using configurations extracted from MD simulations in the amorphous phase.[36,39,47–49]

Framed in this picture, our study is aimed at investigating the four recently proposed TAA-molecules[32–34] depicted in Figure 1. We apply a modern computational approach involving classical and quantum calculations and exploiting the Marcus theory in order to shed light on the structure-properties relationship that rules the charge and exciton transport in these systems in both crystalline and amorphous phases.

The paper is structured as follows: after a description of the employed computational protocol, the calculated transport properties of the four investigated materials are discussed in terms of their electronic, optical and packing properties. The results are presented in the perspective of providing valuable insights to drive the rational design of new and better performing molecules.

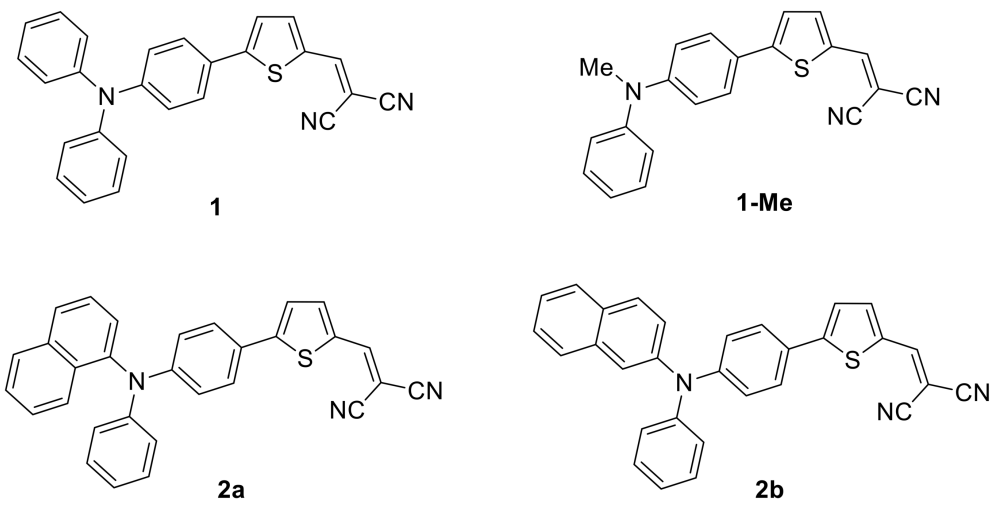

Figure 1: Chemical structures of the four TAA-based donor materials studied in this work.

Computational Methods

The crystal structures of the molecules **2a** and **2b** were obtained following the approach described in Ref. 35, by using the polymorph predictor module in Materials Studio.[50] A single molecule was optimized using the DMol3 module while electrostatic potential charges of all atoms were obtained employing the PBE functional.[51] Crystal structure prediction was thus carried out using the Dreiding force field,[52] considered the most reliable force field for molecular crystal prediction.[53] The polymorph predictor calculations were restricted to the five most probable space groups, i. e. P21/C, P1, P212121, P21, and $P\bar{1}$.[54] We sorted the obtained crystal structures as a function of their total energies and we selected those with the lowest energies.

MD simulations of the amorphous bulk[55] were performed for each compound to calculate the associated hole mobilities. Each system was built starting from a configuration in which 1000 molecules were placed at random positions in a cubic periodic box having an edge of 250 Å . All systems were equilibrated in the NPT ensemble at atmospheric pressure and high temperature (P = 1 atm, T = 800 K) until the volume of the periodic box reached an equilibrium value. Following a further equilibration run at T = 300 K, a 30-ns long trajectory in the NPT ensemble was obtained for each system. All MD simulations employed a

time step of 1 fs. A cutoff of 12 Å was applied to the van der Waals interactions through a switching function, whereas the particle mesh Ewald (PME) method was employed to calculate the electrostatic interactions. The simulations were performed using NAMD2.11 package[56] and the CGenFF force field.[57,58] For all considered systems, the restrained electrostatic potential (RESP) procedure[59] was employed to obtain accurate partial charges (based on HF/6-31G(d,p) results). The equilibrium condition was ensured by verifying that the volume fluctuated around its average value: the plot of the volume of the simulation cell in the 30 ns-long NPT production run shows that the volume is at equilibrium in all the four cases (data in Figure S1 of Supporting Information).

To simulate the hole transport in each of the four systems in crystalline and amorphous phase, we applied the nonadiabatic high-temperature limit of the semiclassical Marcus charge-transfer theory.[42] This theory is based on the assumption that charges are localized on a single molecule and charge-transfer reactions take place via a hopping mechanism according to which the hopping rate between two molecules i and j can be computed as

$$\omega_{ij} = \frac{J_{ij}^2}{\hbar}\sqrt{\frac{\pi}{\lambda k_B T}} exp\left[-\frac{(\Delta E_{ij} - \lambda)^2}{4\lambda k_B T}\right] \quad (1)$$

where T is the temperature, J_{ij} is the electronic coupling element (or transfer integral) between i and j, $\Delta E_{ij} = E_i - E_j$ is the site energy difference, and λ is the reorganization energy.[42]

The reorganization energy is defined as

$$\lambda = E_{nC} - E_{nN} + E_{cN} - E_{cC} \quad (2)$$

where E_{nN} (E_{cC}) is the electronic energy of the neutral (charged) molecule in its optimized neutral (charged) geometry and E_{nC} (E_{cN}) is the energy of the neutral (charged) molecule in the optimized charged (neutral) geometry. For the four molecules λ was calculated employing the density functional theory (DFT) at the B3LYP/6-311g(d,p) level of theory.

The electronic coupling elements were calculated following the approach presented in Ref. 46. The latter assumes that the HOMO orbital of a dimer results exclusively from the interaction of the HOMO orbitals ϕ_i and ϕ_j of the monomers i and j respectively and thus it can be expanded in terms of those. Within this approach $J_{ij} = \langle \phi_i | \hat{H} | \phi_j \rangle$, where $\hat{H}$ is the dimer Hamiltonian. All J_{ij}s were calculated using the semi-empirical ZINDO method.[45,60]

J_{ij} were calculated using the semi-empirical ZINDO method.[45,60] It has been showed that the ZINDO Hamiltonian produce reliable results comparable to the experimental values. This technique is thus suitable to study transport in large scale or complex systems.[45,46]

The site energy difference contains three contributions: 1) the internal site energy difference $(\epsilon_i - \epsilon_j)$, 2) the electrostatic site energy difference calculated within a given volume around the pair using partial charges generated via the Merz-Singh-Kollman scheme[61] and 3) the contributions of an applied external electric field $\vec{E}$ ($\Delta E_{ext} = -e\vec{E} \cdot \vec{r}_{ij}$) where $\vec{r}_{ij}$ is the vector joining the centers of mass of two molecules.

We calculated the Marcus rates for each molecular pair ij from a neighbor list built with a cutoff of 15 Å . In the case of molecular crystals, we neglected the internal and electrostatic contributions to the site energy difference due to the symmetry of the crystalline phase. For the calculation of the charge mobility in the amorphous phase we used molecular configurations extracted from MD simulations.

Finally, we calculated the hole mobilities μ setting up KMC simulations using the obtained rates. The mobility in the direction of the applied external electric field was calculated as

$$\mu = \frac{\langle v \rangle}{E} \tag{3}$$

where $\langle v \rangle$ is the average velocity of the charge in the direction of the applied field $\vec{E}$.

The exciton diffusion coefficients D for the four investigated systems in the crystalline phase were calculated following the approach described in Ref. 44. Likewise the charge transport, the exciton transport can be depicted as a hopping process with a hopping rate

described by Eq.1. In this case the reorganization energy λ is defined as[62–64]

$$\lambda = E_{nX} - E_{nN} + E_{xN} - E_{xX}, \tag{4}$$

where E_{nN} (E_{xX}) is the electronic energy of the molecule in the ground (excited) state of its optimized ground (excited) state geometry and E_{nX} (E_{xN}) is the energy of the molecule in the ground (excited) state of the optimized excited (ground) state geometry. For the four molecules λ was calculated with DFT calculations optimizing the ground and excited state geometries at the CAM-B3LYP/6-311G(d,p) level and calculating the four terms in Eq.4 at the B3LYP/6-311G(d,p) level of theory through single point calculations.

The excitonic couplings J_{ij} are defined as[44,65,66]

$$J_{ij} = \frac{E_{Dim(2)} - E_{Dim(1)}}{2} \tag{5}$$

where $E_{Dim(1)}$ and $E_{Dim(2)}$ are the energies of the two lowest excited states of the dimer resulting from the Davydov splitting[67] of the monomer S_1 levels computed at the CAM-B3LYP/6-311G(d,p) level of theory.

The site energy difference contains only one term derived from the application of a small fictitious drift force $\vec{F}$ ($\Delta E_{ij} = \vec{F}\vec{r}_{ij}$). This term was introduced in Ref. 44: the calculations of the exciton diffusion coefficient by means of a simple diffusion rate equation based on the hopping rates and the squared hopping distance possibly leads to an overestimation of the diffusion constant.[65] To overcome this issue, the authors suggest to apply a small fictitious force $\vec{F}$ as a drift term in order to evaluate an exciton mobility in analogy with the charge mobility. The latter, combined with the Einstein relation, leads to

$$D = k_B T \frac{\langle v \rangle}{F} \tag{6}$$

where $\langle v \rangle$ is the average velocity of the exciton in the direction of $\vec{F}$. Similarly to the

calculation of hole mobility, D was calculated by means of KMC simulations using the obtained rates.

In our charge and exciton transport models we neglected recombination phenomena assuming the same recombination rates for all the studied materials.

In the follow, DFT-based quantities calculated in implicit solvent are computed using the polarizable continuum model (PCM). approach.[68]

Results and Discussion

In order to calculate the hole mobility and the exciton diffusion coefficient in the investigated systems in both crystalline and amorphous phase we first predicted the crystal structure of the molecules 1, 2a and 2b using Material Studio and the procedure described in the Computational Methods section. All the obtained structures belong to the same space group $P\bar{1}$ as the experimentally available crystal structure of the molecule **1-Me**.[32] Table 1 reports the predicted cell parameters for the four crystals depicted in Figure 2.

Table 1: Cell parameters of the predicted crystalline structure of **2a** and **2b** along with the experimental values of **1**[33] and **1-Me**.[32] (Angles are reported in degrees and cell parameters in Å).

System	α	β	γ	a	b	c
1[a]	90.0000	90.0000	110.6000	19.8370	15.6120	7.1912
1-Me[b]	82.5470	84.1080	87.1230	5.7003	8.7382	17.5060
2a	67.6937	73.3101	76.4538	23.2413	8.1118	7.9374
2b	54.9466	82.2253	83.2363	19.1165	12.3813	7.1568

[a] experimental values are taken from Ref. 33
[b] experimental values are taken from Ref. 32

In conjugated molecules, the $\pi - \pi$ packing mode of the dimers inside the crystals plays an important role in determining the hole mobility. In general, configurations characterized by a cofacial $\pi - \pi$ packing allow an optimal π-orbital overlap that in turn ensures relatively large transfer integrals.[35] A first qualitative inspection of the crystals shows that among all molecules, **1-Me** and **2b** have the best geometrical packing that favors face-to-face $\pi - \pi$

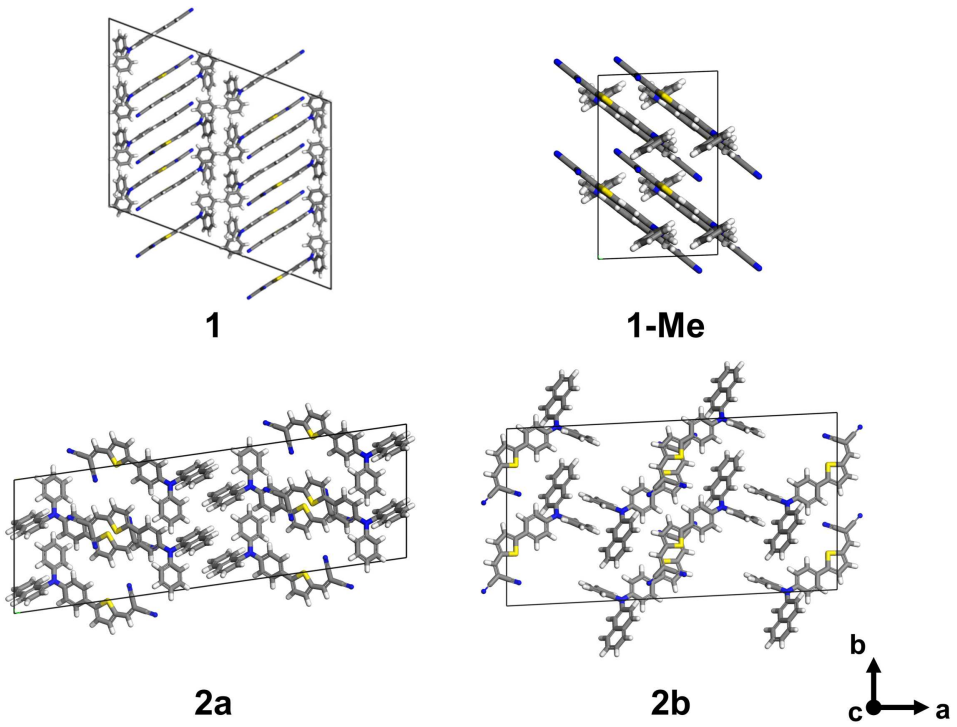

Figure 2: 2×2×2 supercells of the predicted crystalline structures of **2a** and **2b** and of the experimental structures of **1-Me**[32] and **1**.[33]

stacking thus enhancing the transport properties.

Using the obtained crystal structures, we calculated the hole mobilities and the exciton diffusion coefficients of supercells (3×3×5 for **1**, 5×5×3 for **1-Me** and 3×5×5 for the others) along the three crystal axes (μ_a, μ_b, μ_c) as described in the Computational Methods section. For the calculation of the hole mobility we applied an electric field of 10^6 V/m. This value is typical in experimental measurements of charge mobility performed through the time-of-flight (TOF) technique.[60,69] The results along with the average mobilities calculated in the three directions (μ_{av}) and the available experimental values (μ_{exp}) are reported in Table 2.

The calculated μ_{av} values show the same trend of the experimentally observed hole motilities thus supporting the robustness of our calculation protocol.

For the calculation of the exciton diffusion coefficients of the four cristalline systems we employed a force of 16 aN in Eq. 1 as in Ref. 44. The calculated values in the direction of the three crystal axes (D_a, D_b, D_c) and the average values (D_{av}) are reported in Tab.3.

Table 2: Experimental μ_{exp} and calculated hole mobilities along the three crystallographic axes (μ_a, μ_b, μ_c) and their averages (μ_{av}) in $cm^2V^{-1}s^{-1}$. Computed reorganization energies (λ) are given in meV.

System	μ_a	μ_b	μ_c	μ_{av}	μ_{exp}[a]	λ
1	$2.52 \cdot 10^{-5}$	$7.50 \cdot 10^{-5}$	$1.14 \cdot 10^{-4}$	$7.14 \cdot 10^{-5}$	$1.00 \cdot 10^{-5}$	127
1-Me	$6.03 \cdot 10^{-4}$	$2.45 \cdot 10^{-4}$	$4.77 \cdot 10^{-4}$	$4.42 \cdot 10^{-4}$	$5.00 \cdot 10^{-4}$	194
2a	$1.17 \cdot 10^{-5}$	$1.03 \cdot 10^{-5}$	$8.76 \cdot 10^{-6}$	$1.03 \cdot 10^{-5}$	$4.20 \cdot 10^{-6}$	156
2b	$1.68 \cdot 10^{-4}$	$1.14 \cdot 10^{-4}$	$1.09 \cdot 10^{-4}$	$1.30 \cdot 10^{-4}$	$5.50 \cdot 10^{-5}$	120

[a] experimental values from Ref. 32,34

Table 3: Exciton diffusion coefficients calculated along the three crystallographic axes (D_a, D_b, D_c) and the average values D_{av} in m^2s^{-1}. Computed reorganization energies (λ) are given in meV.

System	D_a	D_b	D_c	D_{av}	λ
1	$2.18 \cdot 10^{-5}$	$2.94 \cdot 10^{-5}$	$4.17 \cdot 10^{-5}$	$3.10 \cdot 10^{-5}$	119
1-Me	$6.94 \cdot 10^{-5}$	$1.93 \cdot 10^{-5}$	$1.88 \cdot 10^{-5}$	$3.58 \cdot 10^{-5}$	128
2a	$4.26 \cdot 10^{-5}$	$2.86 \cdot 10^{-5}$	$1.96 \cdot 10^{-5}$	$3.03 \cdot 10^{-5}$	142
2b	$4.22 \cdot 10^{-6}$	$1.77 \cdot 10^{-5}$	$2.95 \cdot 10^{-5}$	$1.71 \cdot 10^{-5}$	138

The calculated D_{av} coefficients are similar for the four systems. In particular **1-Me** shows a slightly higher value in agreement with the highest power conversion efficiency (PCE) measured in solar cells making use of these molecules.[32,34]

On the other hand, it is difficult to find a direct connection between the different transport properties calculated and the chemical structure of the analyzed molecules. First, the difference in both charge and excitonic reorganization energies reported in Table 2 and 3 respectively are too small to justify our results. Moreover, and to some extent unexpectedly, the molecule with the highest λ for hole transport, that is **1-Me**, displays also the highest hole mobility. The rationale that lies behind the different transport properties has thus to be found elsewhere.

At first, we looked for possible differences in the electronic and optical properties of the four molecules. Figure 3 shows the HOMO and LUMO orbitals computed for all systems.

It is clear that there is only a trifling difference in the frontier molecular orbitals among the molecules and that the influence of the substituents in the triphenylamine unit on the

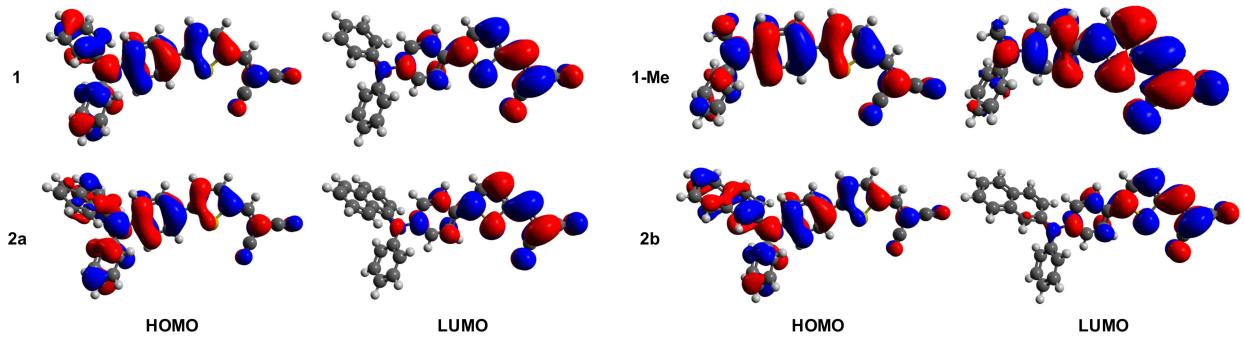

Figure 3: Computed HOMO and LUMO orbitals of the four investigated molecules calculated at B3LYP/6-311G(d,p) level of theory.

overall electronic structure is negligible. Moreover, we calculated (at the B3LYP/6-311G(d,p) level) other relevant parameters that depends on the electronic structure of the investigated molecules and that can influence the performance of a solar cell, namely: the HOMO-LUMO gap (Δ_{H-L}), the adiabatic ionization potential (IP) and the degree of charge delocalization (D_{chg}) defined as the ratio of the number of atoms of the molecule in the cationic state carrying a partial charge larger than 0.1e and the total number of atoms.[36]

Table 4: Energies of the HOMO and LUMO orbitals (E_H and E_L) calculated at the B3LYP/6- 311G(d,p) level along with the HOMO-LUMO gap Δ_{H-L}, the Adiabatic Ionization Potential (IP) expressed in eV and the degree of charge delocalization.

System	E_H	E_L	Δ_{H-L}	IP	D_{chg}
1	-5.57	-2.96	2.61	6.66	0.51
1-Me	-5.62	-2.84	2.77	6.77	0.52
2a	-5.58	-2.94	2.63	6.61	0.51
2b	-5.54	-2.97	2.57	6.57	0.52

The results are in qualitative agreement with the experimental values reported in Ref. 32,34. However, there are no appreciable differences among the studied systems except for **1-Me**: the substitution of an aromatic ring of the triphenylamine unit with a methyl group slightly increase both the Δ_{H-L} and the IP. Apart from that, the substituents in the triphenylamine unit have only a negligible effect on the electronic properties of the HTMs.

It might be argued that the systems could differ in their optical properties. To test this hypothesis, we computed the absorption (λ_{abs}) and emission wavelengths (λ_{em}) and

their difference (Stoke shift), at the TD-B3LYP/6-311G(d,p) level of theory. Their values are reported in Table 5, along with the optical gap, defined as the first singlet excitation energy E_1,[70] and the exciton binding energy E_b. The latter represents the energy required to fully separate the electron-hole pair against Coulomb attraction: it is defined as the energy difference between the neutral exciton and the two free charge carriers (i. e. the electron and the hole). This quantity is expressed as $E_b = E_g - E_1 = \Delta_{H-L} - E_1$. E_g is the electronic band gap, here replaced by the HOMO-LUMO energy gap (Δ_{H-L}).

Table 5: Optical properties calculated at the TD-B3LYP/6-311G(d,p) level of theory in implicit dichloromethane (Polarizable Continuum Model approach[68]): the absorption λ_{abs} and the emission wavelengths λ_{em} based on S_0 and S_1 states along with the Stoke shifts in nm, the first singlet excitation energy E_1 and the exciton binding energy E_b in eV.

System	λ_{abs}	λ_{em}	Stoke shift	E_1	E_b
1	552	580	27	2.24	0.29
1-Me	515	540	25	2.40	0.25
2a	544	585	41	2.27	0.30
2b	559	590	31	2.21	0.29

1, **2a** and **2b** share analogous optical properties but in **1-Me** the substitution of an aromatic ring of the triphenylamine unit with a methyl leads to a blueshift for both emission and absorption. Moreover, there is a slight reduction of the exciton binding energy (E_b), which indicates that the electron-hole separation is favored in **1-Me**, thus increasing the performance of the solar cell.

Again, these small changes observed for the electronic and optical features of the four molecules cannot justify overall their difference in transport properties. These latter can thus be ascribed only to the different molecular packing in their crystalline phases induced by the small modifications in their molecular skeleton. Table 6 reports the centroid to centroid distance (r_{ij}), the square of the electronic coupling elements ($J_{ij}^{2(hole)}$ and $J_{ij}^{2(ex)}$) and the hopping rates ($\omega_{ij}^{(hole)}$ and $\omega_{ij}^{(ex)}$) computed for the main hopping pathways for hole and exciton transport in the four systems showed in Figure 4.

It is clear that among the investigated molecules **2b** and, especially, **1-Me** achieve the

Table 6: Centroid to centroid distance r_{ij} (Å), the square of the electronic coupling elements ($J_{ij}^{2(hole)}$ and $J_{ij}^{2(ex)}$ in meV^2) and the hopping rates ($\omega_{ij}^{(hole)}$ and $\omega_{ij}^{(ex)}$ in s^{-1}) of the main hopping pathway of hole and exciton transport in the investigated systems.

System	r_{ij}	$J_{ij}^{2(hole)}$	$\omega_{ij}^{(hole)}$	$J_{ij}^{2(ex)}$	$\omega_{ij}^{(ex)}$
1	8.39	1.97	$1.74 \cdot 10^{13}$	95.5	$1.98 \cdot 10^{14}$
1-Me	5.70	7.37	$4.31 \cdot 10^{13}$	146.3	$2.92 \cdot 10^{14}$
2a	13.43	0.11	$1.03 \cdot 10^{12}$	117.5	$1.56 \cdot 10^{14}$
2b	10.86	2.28	$3.62 \cdot 10^{13}$	66.1	$5.19 \cdot 10^{13}$

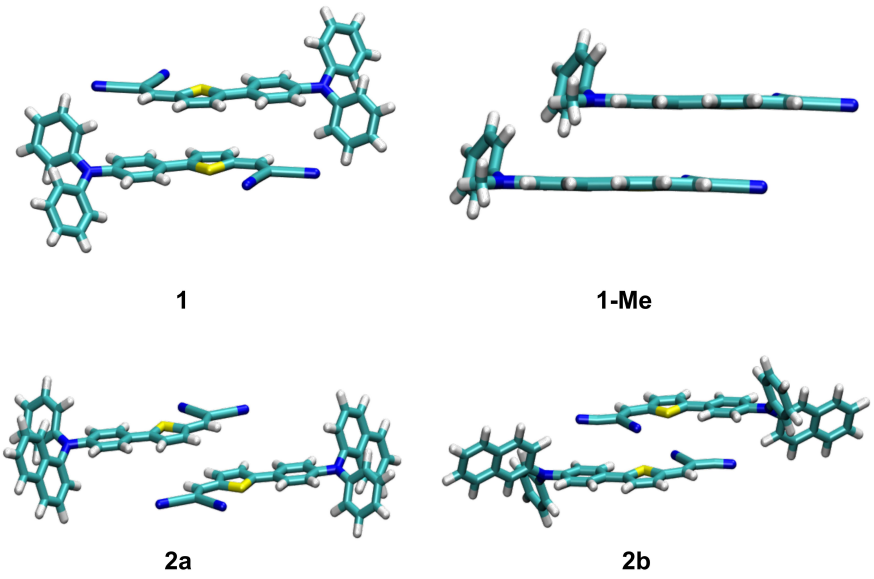

Figure 4: Main hopping pathway of hole transport in the investigated systems.

best packing in the molecular crystal. In particular, the substitution of the phenyl with a methyl in **1-Me** enhances the face to face $\pi - \pi$ packing and allows a good π-orbital overlap and a short centroid to centroid distance thus enhancing the transfer integrals and the hopping rates (see Table 6 and Figure 4). On the contrary, in **1** and **2a** the crystal packing forces the conjugated rings to a more tilted configuration and increase the distance between the centroids, thus negatively affecting the orbital overlap and the transport properties. Notably, there is a sensible difference in the calculated hole mobility between **2a** and **2b**. These two compounds both present a naphtyl group but a different connectivity. The β-

naphtyl compound (**2b**) shows a more coplanar geometry with respect to the α-naphtyl one (**2a**) that leads to a higher hole mobility. This is related to the larger steric hindrance of the α-naphtyl group that generates a more twisted structure, negatively affecting the transport properties.

In the case of the four HTMs in the amorphous phase, for each system we calculated the hole mobility for 1000 configurations extracted from the MD simulations as described in the Computational Methods section. The calculations were repeated applying an electric field of 10^6 V/m in several directions and averaging the resulting mobility values (μ_{amo}). The results are reported in Table7

Table 7: Hole mobilities calculated in the amorphous systems (μ_{amo}, in $cm^2V^{-1}s^{-1}$).

System	μ_{amo}
1	$(8.14 \pm 3.93) \cdot 10^{-11}$
1-Me	$(3.13 \pm 1.31) \cdot 10^{-11}$
2a	$(2.21 \pm 1.47) \cdot 10^{-11}$
2b	$(1.73 \pm 0.69) \cdot 10^{-10}$

The analyzed systems show similar low mobilities indicating a similar degree of local order in the amorphous phase. This is clearly evident from the calculation of the radial distribution function of the nitrogen atom belonging to the triphenylamine groups reported in Figure 5.

The radial distribution function is defined as the ratio[55,71]

$$g(r) = N(r)/g_I(r) \tag{7}$$

where N(r) is the number of occurrences of the radial distance r between pairs of particles and $g_I(r)$ is the radial distribution function of an ideal gas with density ρ: $g_I(r) = 4\pi\rho r^2$. Using this type of normalization $g(r \to \infty) = 1$. The presence of peaks in the $g(r)$ would reveal the presence of ordered structures in the bulk.

Figure 5 shows a similar $g(r)$ for all the investigated systems: the differences in terms of molecular structure among the four molecules are too small to significantly influence the

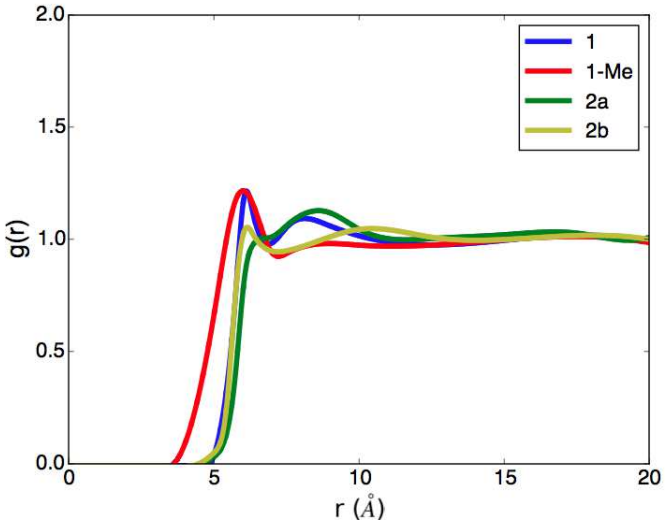

Figure 5: Radial distribution functions $g(r)$ of the nitrogen atom belonging to the triphenylamine groups of the simulated systems calculated from the MD trajectories in the amorphous phase.

local order properties of the amorphous bulks. Their similar low mobility values suggest that the amorphous domains of a typically polycrystalline HTM layer of a solar cell affect in analogous fashion the overall performance of the device.

Taken together, these results suggest that small modifications in the molecular structure of triphenylamine based HTMs are able to strongly affect their transport properties in the crystalline phase. Importantly, our calculations show that the substitution of a phenyl in the triphenylamine unit does not significantly alter the electronic and optical properties of these materials. On the other hand the tiny alteration of the molecular scaffold has a large effect on the molecular packing in the crystal structure. In particular, we show that the substitution of the phenyl with a methyl in **1-Me** enhances the face-to-face $\pi - \pi$ packing in the crystal structure increasing the effective π-orbital overlap and thus raising the hole mobility between conjugated molecules (see Table 6 and Figure 4). Moreover, we show that the molecular modifications do not alter significantly the low hole mobility of these materials in bulk amorphous phase that is completely disordered for all systems.

The theoretical results, in agreement with the experimental findings[32,34] indicate that in

order to improve the transport properties and, consequently, the performance of a solar cell it is important to focus on the crystal phase of the HTM materials designing molecules that are able the achieve the most suitable molecular packing for transport.

Conclusions

In this study, we theoretically investigate the effects of small molecular substitutions in the structure of triphenylamine based hole transporter materials used in organic solar cells on their transport properties in the crystalline and amorphous phases. Exploiting DFT, TD-DFT, MD, and the Marcus theory we analyze the molecular rationale that lies behind the different measured transport properties of four HTMs whose scaffold differs only for the substitution of one phenyl ring in the triphenylamine unit. Our calculations clearly show that the effect of the substituents on the electronic and optical properties of these materials is negligible. On the other hand, chemical modifications have important effects on the molecular packing in the crystalline structure that are able to account for the different calculated transport properties. In particular, we show that the substitution of the phenyl with a methyl in **1-Me** enhances the face-to-face $\pi - \pi$ packing in the crystal structure that allows a good π-orbital overlap at short centroid to centroid distance enhancing the transfer integrals and the hopping rates. On the contrary, the presence of a α-naphtyl in **2a** generates a twisted structure due to the steric hindrance that negatively affects its transport properties.

Moreover we find that the difference in the molecular structure of the four molecules is too small to significantly influence the degree of local order in the amorphous bulks all characterized by a completely disordered morphology and low mobilities. In fact, the amorphous phase is more sensitive to the overall shape of the molecules rather than to the effective chemical substitutions. In the case of the materials studied in this work, the modification of the molecular shape is too slight to affect the amorphous phase.

These results, in line with the experimental findings, suggest that in the quest of new performing materials able to improve the performances of a solar cell it is desirable to devise a strategy that, starting from little transformations of a molecular scaffold, leads to the optimization of the packing properties in the crystal phase and, consequently, to improved transport properties and more efficient solar cells.
