Dear Author,

Here are the proofs of your article.

- You can submit your corrections **online**, via **e-mail** or by **fax**.
- For **online** submission please insert your corrections in the online correction form. Always indicate the line number to which the correction refers.
- You can also insert your corrections in the proof PDF and **email** the annotated PDF.
- For fax submission, please ensure that your corrections are clearly legible. Use a fine black pen and write the correction in the margin, not too close to the edge of the page.
- Remember to note the **journal title**, **article number**, and **your name** when sending your response via e-mail or fax.
- **Check** the metadata sheet to make sure that the header information, especially author names and the corresponding affiliations are correctly shown.
- **Check** the questions that may have arisen during copy editing and insert your answers/ corrections.
- **Check** that the text is complete and that all figures, tables and their legends are included. Also check the accuracy of special characters, equations, and electronic supplementary material if applicable. If necessary refer to the *Edited manuscript*.
- The publication of inaccurate data such as dosages and units can have serious consequences. Please take particular care that all such details are correct.
- Please **do not** make changes that involve only matters of style. We have generally introduced forms that follow the journal's style. Substantial changes in content, e.g., new results, corrected values, title and authorship are not allowed without the approval of the responsible editor. In such a case, please contact the Editorial Office and return his/her consent together with the proof.
- If we do not receive your corrections **within 48 hours**, we will send you a reminder.
- Your article will be published **Online First** approximately one week after receipt of your corrected proofs. This is the **official first publication** citable with the DOI. **Further changes are, therefore, not possible.**
- The **printed version** will follow in a forthcoming issue.

Please note

After online publication, subscribers (personal/institutional) to this journal will have access to the complete article via the DOI using the URL: [http://dx.doi.org/\[DOI\]](http://dx.doi.org/[DOI]).

If you would like to know when your article has been published online, take advantage of our free alert service. For registration and further information go to: <http://www.link.springer.com>.

Due to the electronic nature of the procedure, the manuscript and the original figures will only be returned to you on special request. When you return your corrections, please inform us if you would like to have these documents returned.

Abstract Gastrotricha and Platyhelminthes form a
9 clade called Rouphozoa. Representatives of both taxa
10 are main components of meiofaunal communities, but
11 their role in the trophic ecology of marine and
12 freshwater communities is not sufficiently studied.
13 Traditional collection methods for meiofauna are
14 optimized for Ecdysozoa, and include the use of
15 fixatives or flotation techniques that are unsuitable for
16 the preservation and identification of soft-bodied
17 meiofauna. As a result, rouphozoans are usually

underestimated in conventional biodiversity surveys 18
and ecological studies. Here, we give an updated 19
outline of their diversity and taxonomy, with some 20
phylogenetic considerations. We describe success- 21
fully tested techniques for their recovery and study, 22
and emphasize current knowledge on the ecology, 23
distribution, and dispersal of freshwater gastrotrichs 24
and microturbellarians. We also discuss the opportu- 25
nities and pitfalls of (meta)barcoding studies as a 26
means of overcoming the taxonomic impediment. 27
Finally, we discuss the importance of rouphozoans in 28
aquatic ecosystems and provide future research direc- 29
tions to fill in crucial gaps in the biology of these 30
organisms needed for understanding their basic role in 31
the ecology of benthos and their place in the trophic 32
networks linking micro-, meio-, and macrofauna of 33
freshwater ecosystems. 34

37 Introduction

38 Meiofauna constitutes a significant reservoir of biodi-
39 versity in aquatic ecosystems that is often overlooked.
40 Sediments and vegetation in freshwater habitats,
41 including freshwater ponds, lakes, and rivers, but also
42 mosses, wet soils and semi-aquatic agricultural
43 ecosystems (e.g., paddy fields), are teeming with
44 hundreds of thousands, if not millions of poorly known
45 or completely unrecorded species of these micro-
46 scopic animals (Giere, 2009).

47 Traditional morphology-based sampling tech-
48 niques to study biodiversity and ecology of meiofauna
49 are usually addressed towards ecdysozoan taxa such as
50 nematodes and copepods, and have so far failed to
51 account for the sometimes equally abundant and
52 diverse soft-bodied gastrotrichs and meiofaunal flat-
53 worms or so-called “microturbellarians” (Martens &
54 Schockaert, 1986; Nesteruk, 2006; Schockaert et al.,
55 2008; Giere, 2009). Perhaps more so than other
56 meiofaunal groups, gastrotrichs and microturbellari-
57 ans also exemplify the taxonomic impediment, includ-
58 ing a lack of knowledge on their biodiversity and
59 organismal biology, a lack of experts and a lack of
60 taxonomic infrastructure. As such, they have lagged
61 behind in species discovery and identification, uncov-
62 ering (cryptic) speciation, biodiversity surveys, pop-
63 ulation genetics, and phylogeography. Traditional
64 morphology-based identification methods are often
65 time-, effort-, and resource-intensive, depend on a
66 handful of taxonomic experts, and cannot uncover
67 cryptic diversity. As shown by a few comprehensive
68 studies of single taxa, the current number of described
69 species of these two groups in fresh waters is
70 significantly lower than the estimated species diversity
71 (e.g., Catenulida: Larsson et al., 2008; *Microstomum*:
72 Atherton & Jondelius, 2018, 2019; Gastrotricha:
73 Balsamo et al., 2008).

74 In this contribution, we will focus on the micro- and
75 meiofaunal freshwater representatives of these taxa
76 and largely omit the numerous members of the
77 macrofaunal flatworm group Tricladida, which,
78 because of their large size, have been rather well
79 studied and are far better known worldwide.

Freshwater gastrotrichs and microturbellarians not
only share a number of morphological and biological
traits, but their parent phyla, Gastrotricha and Platy-
helminthes, also recently emerged in a monophyletic
clade within the Spiralia called Rousphozoa (Gr.
Rouphao, ingesting by sucking; Struck et al., 2014),
which was endorsed by two subsequent, independent
phylogenomic studies (Egger et al., 2015; Laumer
et al., 2015a). However, Bleidorn (2019) recovered a
clade comprising Nemertea and Platyhelminthes sep-
arate from the clade of Gastrotricha; thus, it is clear
that further molecular and morphological work is
needed to test the monophyly of the Rousphozoa. The
duo-gland adhesive system, recently studied in detail
for platyhelminthes (Wunderer et al., 2019), was
proposed as a possible synapomorphy for both taxa
(Giribet & Edgecombe, 2019). However, studies of the
gastrotrich duo-gland system are much older (Tyler &
Rieger, 1980; Ruppert, 1991). Consequently, detailed
molecular studies of the duo-gland system in Gas-
trotricha and research to identify other possible
synapomorphies within Rousphozoa are sorely needed.

Because of their abundance, small body size and
selective micro- and meiophagous feeding behavior,
gastrotrichs and microturbellarians most likely play a
critical role in freshwater trophic networks and
ecosystem dynamics (Palmer et al., 1997; Balsamo
& Todaro, 2002; Majdi et al., 2019). However, their
diversity and ecological roles in aquatic ecosystems
are still insufficiently known. For freshwater gas-
trotrichs, the results of the few targeted studies on
functional ecology appear controversial (Strayer,
1985; Hummon, 1987; Nesteruk, 1996a, 2007b; Sch-
mid-Araya, 1997), and for freshwater microturbellari-
ans no such studies exist to date.

In this study, we aim to give an overview of the
current state of knowledge on the diversity, distribu-
tion, and ecology of freshwater rousphozoans. This
includes an updated census of species in the various
biogeographical regions, a summary on the impor-
tance of environmental parameters and biotic interac-
tions on habitat preferences, spatial and temporal
distribution, dispersal and trophic ecology of these two
groups. We also provide recommendations to over-
come methodological problems and challenges in
qualitative and quantitative collection and identifica-
tion of these animals, and discuss future research
avenues to fill in crucial gaps in our knowledge on
these important freshwater animals.

129 Methodologies for sampling and study

130 It is clear that in studies of freshwater meiofauna,
 131 Rousphozoa are frequently not considered (Fig. 1). As
 132 already noted by some authors (e.g., Traunspurger &
 133 Majdi, 2017), we hypothesize that this is because
 134 extraction methods used for these soft-bodied organ-
 135 isms are very different from those used for ecdysozoan
 136 taxa. This is further supported by historical studies that
 137 recovered large numbers of rousphozoan taxa using
 138 extraction methods compatible with their preservation
 139 (e.g., Strayer, 1985; Robertson et al., 2000). Finally,
 140 metabarcoding studies in a marine context routinely
 141 recover rousphozoans thought previously to be rare
 142 based solely on morphotaxonomic studies (e.g.,
 143 Rzeznik-Orignac et al., 2017; Leasi et al., 2018).
 144 Accordingly, we provide up-to-date methods below
 145 **AQ2** for the collection, preservation, and study of rouspho-
 146 zoans (Tables 1, 2).

147 Sampling and extraction

148 Due to the patchy distribution of meiofauna, collec-
 149 tions of many small samples during different times of
 150 the year are preferred over a single large sample
 151 (Giere, 2009). For the same reason the choice of
 152 sampling sites is also very important, and should touch

all the habitats of a single biotope. (Heitkamp, 1988). 153
 The main criteria for qualitative/quantitative sampling 154
 of microturbellarians and gastrotrichs are summarized 155
 in Table 1. 156

157 Individuals of both groups are more successfully
 158 studied alive in fresh samples than in preserved
 159 samples, since their body frailty and strong contrac-
 160 tility often cause diagnostic morphological characters
 161 to be distorted after fixation (Balsamo & Todaro,
 162 2002, Balsamo et al., 2014). In the laboratory,
 163 collected fresh samples are moved into bowls
 164 equipped with an aeration system and a lighting neon
 165 tube if also vegetation is present. The bowls are filled
 166 with additional filtered water from the sampling site
 167 (or spring water if necessary) and kept at room
 168 temperature.

169 A comparative summary of methods for extraction
 170 and study of freshwater microturbellarians and gas-
 171 trotrichs is reported in Table 2. Extraction of animals
 172 from fresh samples implies direct observation of small
 173 amounts of sediment under a stereomicroscope and
 174 picking up single living individuals for subsequent
 175 observation and study under a compound microscope.

176 The extraction of all the animals from a sample is
 177 clearly critical for quantitative analyses, but regret-
 178 tably, the techniques currently available are not
 179 satisfactory for gastrotrichs. A comparative study of

Fig. 1 Google Scholar entries for meiofaunal studies mentioning a. nematodes and/or copepods; b. micro- or macro-turbellarians; c. gastrotrichs. Methods: Publish or Perish (Harzing, 2007) was used (3.5.20) to search Google Scholar, covering years 1985 through 2020, with the following search strings: **A:** (meiofauna OR meiobenth) AND (freshwater OR lake OR river OR stream)

AND (copepod OR nematod) AND NOT marine; 1985–2020; **B:** (meiofauna OR meiobenth) AND (freshwater OR lake OR river OR stream) AND (turbellaria OR platyhelminthes OR microturbellaria) AND NOT marine; **C:** (meiofauna OR meiobenth) AND (freshwater OR lake OR river OR stream) AND (gastrotrich OR gastrotricha) AND NOT marine

Table 1 A comparative summary of qualitative and quantitative methods for sampling freshwater gastrotrichs and microturbellarians

	Gastrotrichs	Microturbellarians
Qualitative methods		
N° sampling sites	A sampling site from each habitat of the biotope	A sampling site from each habitat of the biotope
N° samples	At least 3 small samples per site rather than a single large sample	At least 3 small samples per site rather than a single large sample
Frequency of sampling	Seasonal or summer/winter	Bimonthly, monthly, or seasonal
Type of sampling	Dragging the upper sediment surface [epibenthic species] or repeatedly filtering water around aquatic vegetation [periphytic species] with a net with a handle (30 µm mesh)	Hand picking sediments, organic substrate, aquatic vegetation in the littoral zone, coring in deeper zones
	Pushing a manual corer to 5–10 cm into the sediment and taking a core	Plankton tows (63 µm mesh) through water column and in between aquatic vegetation
	Digging a hole in the sandy sediment and filtering the percolating water through the same net cited above [interstitial species]	Digging a hole in the sandy sediment and filtering the percolating water through the same net cited above [interstitial species]
Quantitative methods	Collecting a number of small subsamples in unsieved conditions for a direct counting of individuals	Collecting a number of small subsamples in unsieved conditions for a direct counting of individuals
	Quantitative samples of periphytic species may be obtained by modifying sampling methods for macroinvertebrates (García-Criado & Trigo, 2005), using fine mesh (30 µm) nets for small sample volumes or subsamples	Standardized volumes of sediment, organic debris, aquatic vegetation or water
	True planktonic species can also be collected with the techniques of quantitative plankton sampling (Sandlung, 1982)	Adjust volumes to the size of the water body and number of (micro-)habitats to avoid sample bias in smaller pools
	Collecting and fixing a massive sample in formalin 4%. Not recommended due to the specimens' coarctation	

180	different techniques aimed at this purpose showed that	placed in a tall beaker with clear transparent walls; the	195
181	a rapid forcing of small quantities of sediment through	beaker is then filled with water from the habitat and	196
182	a 130 µm sieve appears to be the most effective way	allowed to stand, creating a vertical cline of dissolved	197

194	depletion. A layer of sediment and bottom debris are	platyhelminthes in aquatic environments in	207

Table 2 A comparative summary of methods for extraction and study of freshwater gastrotrichs and microturbellarians

Gastrotrichs	Microturbellarians
Qualitative methods	
Extraction	
Treatment of the fresh sample with MgCl ₂ 1% for relaxing specimens, swirling, stereomicroscopical observation of the supernatant (interstitial species)	Decantation and sieving (63 µm mesh) of sediments, organic substrate, and aquatic vegetation agitated in water
Stereomicroscopical observation of small sediment amounts (2–3 cm ³) for search of living specimens (epibenthic and periphytic species)	Hand picking of specimens forced out of organic substrates and aquatic vegetation by oxygen depletion (Schockaert, 1996)
Stereomicroscopical observations of small amounts of plankton net filtrate for search of living specimens (planktonic species)	Stereomicroscopical observations of small amounts of plankton net filtrate for search of living specimens (planktonic species)
Study	
Mounting single live specimens on a slide, observation in vivo under a compound microscope; the use of drops of a 1% aqueous solution of MgCl ₂ can help slowing active specimens	Observations of live specimens under a stereomicroscope and mounted on a slide under a compound microscope
Digital imaging and taking measurements under a compound microscope	Digital imaging and taking measurements under a compound microscope
Quantitative methods	
Extraction	
Density gradient centrifugation of small samples or subsamples preserved with formalin 1% then repeatedly washed. Partially useful only for interstitial species. No really efficient technique available for epibenthic, periphytic, and semiplanktonic species (Giere 2009)	No single technique is suitable to extract all microturbellarians. A variety of techniques should be used to obtain representative numbers of different species.
Study	
Mounting specimens on a slide, observation, videorecording, taking measurements and photos. Internal anatomy not yet clearly visible in preserved specimens.	Mounting specimens on a slide, observation, videorecording, taking measurements and photos of diagnostic measurements on live animals and on whole mounts.

208 percentages that would otherwise go unnoticed with
 209 traditional morphotaxonomic methods (Leray &
 210 Knowlton, 2015; Arroyo et al., 2016; Martínez et al.,
 211 2020; Fegley et al., submitted). As such, (meta)bar-
 212 coding holds great promise to increase our knowledge
 213 on the diversity, ecology, and role of rousphozoans in
 214 aquatic ecosystems (Martínez et al., 2020). This
 215 approach has been reviewed recently (Schenk &
 216 Fontaneto, 2019): accordingly, we here limit ourselves
 217 to considering the promises and pitfalls of DNA-based
 218 methods for evaluation of cryptic diversity and
 219 community composition among gastrotrichs and
 220 microturbellarians, including limitations not men-
 221 tioned in the paper referenced above.

Choice of amplicon 222

The ubiquity of MiSeq technology, with up to 300 bp 223
 paired-end reads, enables useful sequences to be 224
 recovered for most taxa from the V4/V5 region of 225
 the 18S rDNA molecule (for Rousphozoa, < 600 bp; 226
 Hugerth et al., 2014), as opposed to the V9 region 227
 (~ 120 bp; Amaral-Zettler et al., 2009) or V2/V4 228
 (~ 400 bp; Creer et al., 2010). The greater taxonomic 229
 resolution conferred by V4/V5 is also illustrated by the 230
 fact that a recent metabarcoding trial of this amplicon 231
 on a well-studied marine beach in North Carolina, 232
 USA was able to distinguish between congeneric pairs 233
 of microturbellarian species in three cases, two of 234
 which had already been documented morphologically, 235
 and the third documented by 18S rDNA sequencing of 236
 single individuals (Fegley et al., submitted). The same 237

238 study revealed the existence of numerous separate
 239 species of both taxa from two beaches in North
 240 Carolina (Online Resources 1, 2). Accordingly, at least
 241 for Rousphozoa, V4/V5 might be a better choice over
 242 the more commonly used COI barcode because of
 243 poor primer performance with platyhelminthes in
 244 general (Vanhove et al., 2013) and because COI-based
 245 species delimitation may inflate actual diversity,
 246 compared to 18S and 28S rDNA (Van Steenkiste
 247 et al., 2018). However, the development of nanopore
 248 sequencing now makes it possible to produce very
 249 long reads—4 Kb of the rDNA cluster (Kreihenwinkel
 250 et al., 2019), or individually indexed reads of the full-
 251 length “Folmer” region of COI (Maestri et al., 2019;
 252 Kennedy et al., 2020). Because of the increased read
 253 length, nanopore sequencing is also far more tolerant
 254 of amplicon read-length variation than the current
 255 standard of MiSeq 300 bp paired-end sequencing—
 256 for instance, in the North Carolina study noted above,
 257 we obtained relatively few OTUs for crustaceans, as
 258 the V4/V5 region in this taxon is too long for 300 bp
 259 paired-end reads to overlap. This research area is
 260 developing rapidly, and because of portability and low
 261 cost, we urge that MinION sequencing be thoroughly
 262 tested as a routine method for biodiversity assessment
 263 of meiofauna in general.

264 *Pitfalls*

265 Although metabarcoding studies have the ability to
 266 reveal taxa that have not been observed with morpho-
 267 logical taxonomy (see above), they also are liable to
 268 miss taxa that are present. For instance, Lindgren
 269 (1972) reported (“approximately”) 35 species of
 270 microturbellaria and 20 species of gastrotrichs from
 271 ISP beach, so the counts of species shown in Online
 272 Resources 1, 2 are likely an underestimate of actual
 273 species presence. More directly, a recent study on
 274 meiofaunal biodiversity along the Pacific and Atlantic
 275 coast of Panama showed that for all investigated sites,
 276 the diversity of Gastrotricha, Mollusca, Nemertea, and
 277 Xenacoelomorpha estimated by metabarcoding the V9
 278 region of the 18S rRNA was lower than the diversity
 279 based on morphological taxonomy (Leasi et al., 2018).

280 DNA (meta)barcoding relies completely on metic-
 281 ulously curated DNA reference databases that link
 282 sequences to species identified based on morpholog-
 283 ical characters. DNA extractions of tiny animals such
 284 as rousphozoans are routinely performed on full

individuals, thereby rendering physical vouchering
 of morphological characters of the same individual
 impossible. Live and transparent animals with clear
 diagnostic features can easily be documented digitally,
 but opaque animals, (pseudo-) cryptic species, and
 species groups with uncertain taxonomic features pose
 more specific challenges, especially when they are rare
 or are co-occurring in space and time. However, DNA
 extractions of soft-bodied rousphozoans can be non-
 destructive, for instance by performing microdissec-
 tions using the head for DNA extraction and the
 posterior part for morphological study (e.g., macros-
 tomids in Schärer et al., 2011; Janssen et al., 2015),
 and could be a practical solution to incorporate
 “problem” individuals and species into DNA refer-
 ence collections.

Recently, analysis of marine and freshwater metabar-
 coding data has shown its potential for DNA-based
 species discovery and uncovered the existence of two
 hitherto unknown higher-level flatworm groups in
 freshwater (Mitsi et al., 2019). Combined with data on
 abiotic and ecological data, it can provide previously
 unattainable insights into spatial and temporal changes
 in species compositions and link environmental
 parameters with the occurrence of specific taxa
 (Chariton et al., 2015). This can generate novel
 ecological information for taxa such as gastrotrichs
 and microturbellarians that are small, difficult to
 identify, and may only be present as resting eggs or
 other propagules during certain times.

However, metabarcoding and its applications in
 ecology are still in development and need to overcome
 several challenges, many of which apply to meiofauna
 in general and rousphozoans in particular (see Ruppert
 et al., 2019 for a review). DNA reference databases for
 gastrotrichs and microturbellarians are still poorly
 populated and need to be strengthened through global
 collaborations of taxonomic specialists. As this is an
 ongoing and future effort, students and researchers
 will need to be trained in fundamental biodiversity
 research, including careful identification of individu-
 als selected for building DNA barcode databases.
 Other well-known issues include PCR primer bias and
 design, marker choice, standardization of methods,
 and integration with ecological data (Schenk &
 Fontaneto, 2019).

332 Methods for identification

333 *Gastrotricha*

334 The phylum Gastrotricha currently comprises over
 335 850 free-living species widespread in aquatic ecosys-
 336 tems. The division into two classes, Macrodasyoidea
 337 and Chaetonotidae, each including a single order
 338 (Macrodasysida and Chaetonotida, respectively) dates
 339 back to Remane (1925), and follows the evident
 340 differences in morphology, biology, and ecology
 341 between the two taxa (Balsamo et al.,
 342 2009, 2014, 2015; Hummon & Todaro, 2010; Kieneke
 343 & Schmidt-Rhaesa, 2015) (Fig. 2), which has also
 344 been confirmed by molecular analyses (Paps &
 345 Riutort, 2012).

Fig. 2 Schematic view of freshwater Gastrotricha: **a** Chaetonotida, **b** Macrodasysida. AdT, adhesive tubes; CPI cephalic plates; I intestine; Oo oocyte; Ph pharynx; PhIJ pharyngo-intestinal junction; PhP pharyngeal pores; SBr sensory bristles; SC sensory cilia; XO X-organ

Taxonomy and systematics of Gastrotricha have
 been traditionally founded on morphological charac-
 ters, which still represent the basis to systematize
 species and superspecific taxa (Hochberg & Litvaitis,
 2000; Kieneke et al., 2008). Diagnostic characters are
 the general body shape, the morphology of the body
 cuticle and cuticular elements, the shape and length of
 the caudal appendages, the arrangement of the ventral
 ciliation, and the structure of the pharynx. Current
 taxonomy also makes use of molecular techniques,
 and has introduced over time several changes and
 integrations to the traditional classification (e.g.,
 Kånneby et al., 2013; Todaro et al., 2012, 2015).
 These suggest that genera including both marine and
 freshwater species (i.e., *Chaetonotus*, *Aspidiophorus*,
Heterolepidoderma) never form monophyletic clades,
 but rather cluster according to habitat. It is clear that
 the intraphylum phylogeny is not yet resolved as are
 deep ingroup phylogenetic relationships; therefore, a
 stabilization of gastrotrich taxonomy, especially of
 Chaetonotida, has not yet been reached.

Details on the anatomy and biology of freshwater
 gastrotrichs are reported in Balsamo et al. (2014) and
 Kieneke & Schmidt-Rhaesa (2015). A general key to
 gastrotrich families and genera was recently published
 by Todaro et al. (2019). Keys to the freshwater
 gastrotrich fauna also exist (see Balsamo et al., 2014
 for a references' summary), but they are generally
 limited to selected taxa or to limited geographic ranges
 such as the Neotropics (Garraffoni & Araújo, 2010),
 the Nearctic (Kånneby, 2016), and the Palearctic
 (Balsamo et al., 2019). The Gastrotricha Portal (<http://www.gastrotricha.unimore.it>) and the World Register
 of Marine Species (WoRMS, 2020a) contains lists of
 marine and freshwater species, but does not provide
 identification keys.

382 *Platyhelminthes*

The free-living members of the phylum Platy-
 helminthes comprise ~ 6500 species, of which ~
 1500 species occur in freshwater or limnoterrestrial
 environments when also including the macrofaunal
 triclad. Freshwater microturbellarians can be found in
 7 flatworm groups: Catenulida, Macrostomorpha,
 Prorhynchida, Proseriata, Rhabdocoela, Prolecitho-
 phora, and Bothrioplanida. Given the phylogenetic
 relationships among and within these 7 major flat-
 worm groups, incursions of the freshwater

Fig. 3 Clades of microturbellaria with pharynx simplex and homocellular female gonads (yolk contained in oocytes). **a–d** Catenulida: **a** *Catenula confusa*, showing anterior statocyst (st), mouth (mo), and best-developed fission plane (arrow). Scale = 200 µm. **b** Anterior end of *Catenula lemnae*, a species with consecutive well-developed fission planes (arrows). **c** *Stenostomum* cf. *virginianum*, a genus with a well-developed pharynx simplex (ph). Scale = 200 µm; **d** Enlargement of **c**, to show multilobed brain (br), refractile bodies (arrows), and mouth. **e–f** Macrostomorpha: **e** *Macrostomum* sp., with anterior pigmented eyes and pharynx simplex close behind (ph), paired testes (te), and ovaries (ov). Scale = 500 µm (approximate). **f** *Microstomum* sp. with anterior pharynx simplex (ph), three fission planes (fp) in different stages of development. Scale = 250 µm (approximate). Clades with complex pharynges and heterocellular female gonads (separate yolk cells and oocytes). **g** Prorhynchida: *Geocentrophora* cf. *applanata* with complex pharynx (ph) opening anteriorly, median germovitelarium marked by nuclei of germocytes (arrowheads), and light-colored testes follicles (te) associated with lateral branches of the digestive tract. Scale = 500 µm (approximate). **h–i** Rhabdocoela, Kalyptorhynchia: **h** *Opisthocystis* cf. *goettei*, with anterior cone-shaped muscular proboscis (pr), and median rosulate (wreath-shaped) muscular pharynx (ph). Scale = 500 µm (approximate); **i** enlarged view of mid-body region of **h**, showing pharynx, paired testes, and paired germaria (ge). **j–m** Rhabdocoela, Limnotyphloplanida: **j** Dalyelliidae; cf. *Microdalyellia rossi*, showing anterior doliiform (barrel-shaped) pharynx and mature egg (e.g.). Scale = 500 µm (approximate). **k–l** Typhloplanidae: **k** Typhloplaniid showing lateral rope-like vitellaria (vi), one of two paired testes, and posterior rosulate (wreath-shaped) pharynx with genital region shortly behind pharynx; **l** cf. *Ascophora elegantissima* overview showing paired testes, rosulate pharynx, and genital region (go). Scale = 500 µm (approximate); **m**. enlarged view of **l**, showing testes, pharynx, and genital region

393 environment almost certainly happened multiple times
394 from different marine and/or brackish water ancestors
395 (Schockaert et al., 2008; Laumer et al., 2015b).
396 Conversely, returns to brackish water and marine
397 environments have also happened (Van Steenkiste
398 et al., 2013).

399 It is possible to key most platyhelminthes to family
400 level based on morphological characters alone (e.g.,
401 Cannon, 1986; Smith et al., 2020). Useful characters
402 are the presence/absence of a statocyst, the construc-
403 tion of the pharynx, the structure of the female gonad,
404 and the morphology of the male reproductive system
405 (Fig. 3). The basic anatomy of Platyhelminthes,
406 including microturbellaria, is covered in detail else-
407 where (e.g., Rieger et al., 1991).

408 Although DNA taxonomy has been used to trace
409 species radiations in Gastrotricha (Atherton, 2015), it

has only been employed a few times for (cryptic) 410
species delimitation in freshwater gastrotrichs (Kån- 411
neby et al., 2012) and microturbellarians (Larsson 412
et al., 2008; Atherton & Jondelius, 2018, 2019). This 413
illustrates the urgency of improving aspects of envi- 414
ronmental high-throughput sequencing before this 415
potentially cost-effective approach could be widely 416
applied for species discovery, biodiversity surveys, 417
and ecosystem assessments in aquatic ecosystems. 418

Well-supported intraphylum relationships among 419
most major subtaxa (with the exception of the relative 420
position of Rhabdocoela and Proseriata) are provided 421
by two recent transcriptomic studies (Egger et al., 422
2015, Laumer et al., 2015b—Fig. 4). Recent molec- 423
ular phylogenies, albeit largely based on only a few 424
genes, have provided valuable information on rela- 425
tionships within the major groups, often in conflict 426
with the traditional morphology-based taxonomy:
Catenulida (Larsson & Jondelius, 2008), Macrosto- 428
morpha (Janssen et al., 2015; Atherton & Jondelius, 429
2019), Rhabdocoela (Willems et al., 2006; Van 430
Steenkiste et al., 2013; Tessens et al., 2014), and 431
Proseriata (Laumer et al., 2014; Scarpa et al., 2016). 432
Accordingly, it has proven to be challenging to 433
provide morphological apomorphies for many of the 434
resulting clades. Therefore, phylogenomics based on 435
much larger molecular datasets and advances in the 436
study of morphological characters should be inte- 437
grated to provide a more robust taxonomy for different 438
microturbellarian groups. 439

A general key for freshwater microturbellarians is 440
missing at this date, and existing keys focus on specific 441

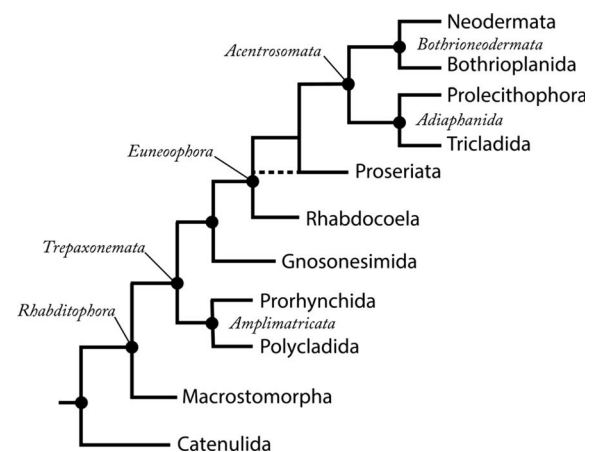

Fig. 4 Major higher-level taxa in Platyhelminthes, based on transcriptomic studies (Egger et al., 2015; Laumer et al., 2015b)

442 taxa or regions. A recent key to freshwater Platy-
443 helminthes of the Nearctic extends to genus, and
444 includes a species list (Noreña et al., 2015). At present,
445 there is no genus-level key to the Palearctic, which is
446 unfortunate, as the majority of collecting and taxo-
447 nomic work has been done there. The Turbellarian
448 Taxonomic Database (Tyler et al., 2006–2016) and the
449 World Register of Marine Species (WoRMS, 2020b)
450 includes worldwide coverage of marine, freshwater,
451 and limnoterrestrial Platyhelminthes, but does not
452 provide a key.

453 Ecology

454 Studies on gastrotrich and microturbellarian autoecol-
455 ogy and synecology are not numerous (Schwank,
456 1981b, 1982a; Heitkamp, 1982, 1988; Ricci &
457 Balsamo, 2000; Kolasa, 2002; Nesteruk, 2016a, b,
458 2017). Abiotic and ecological factors define the
459 qualitative and quantitative compositions of popula-
460 tions, whose mean densities widely vary depending on
461 the characteristics of the habitat and seasonal dynam-
462 ics, and can range from a few thousand up to 2.6
463 million ind/m² for both benthic and pelagic gas-
464 trotrichs (Nesteruk, 2004a, 2009, 2011) and at least

several thousand ind/m² for microturbellarians (Ko-
lasa, 2002); however, several studies use different
units impeding a reliable comparison of values
(Nesteruk, 1993).

Habitat

Various environmental parameters play an important
role in defining the ecological niche of each species of
freshwater rousphozoan and thus they determine their
small-scale and regional diversity and distribution
patterns: these parameters are summarized in Table 3.

Temperature is essential for the colonizing ability
of gastrotrich populations and influences the length
and intensity of reproductive activity rather than their
lifespan (d'Hondt, 1971; Hummon, 1986; Balsamo &
Todaro, 1988). Only a few freshwater species, mainly
the epibenthic ones, are known to tolerate low oxygen
concentrations, unlike some marine species that have
well adapted to this particular habitat (Kraus &
Colacino, 1984). Grain size, shape and sorting, as
well as the amount of organic matter in the substrate
determine the interstitial space available to the few
interstitial species in coarse to medium-fine sands
(Balsamo, 1990; Balsamo & Fregni, 1995; Nesteruk,
2007a, b). The pH can vary significantly in fresh

Table 3 A comparative summary of the main environmental parameters defining the occurrence and distribution of freshwater gastrotrichs and microturbellarians

	Gastrotrichs	Microturbellarians
Temperature	23–28°C (optimum 20–25 °C)	Variable Steno- to eurytherm with variable optimum for reproduction and population growth
Oxygen concentration	High (most species) Low/very low (few tolerant species)	Very high (stream species) High (most species)
pH	4–10 (optimum 6–8)	Unknown for most species 6—(lotic species)
Salinity	Few euryhaline freshwater species	Few euryhaline freshwater species
Water regime	Lentic (most species) Epibenthic/periphytic/planktonic, few interstitial species Lotic (few interstitial species)	Lentic (most species) Mostly epibenthic/periphytic, very few planktonic species Few specialized species in fast-running water
Grain size sediment	Medium-fine (interstitial species) Fine, muddy (epibenthic species)	Variable (lentic species) Optimum of 0.4–0.7 mm for stream species
Organic matter	Oligotrophic (interstitial species) Polytrophic (epibenthic/periphytic species)	Oligotrophic (stream species) Polytrophic (lentic and slow river species)

489 waters; most species live in moderately acidic habi- 538
 490 tats, but some species can tolerate pH values down to 539
 491 4, while others live in alkaline water up to pH 10 540
 492 (Kisielewski, 1981; Nesteruk, 2004a). A few fresh- 541
 493 water gastrotrich species are able to survive or even to 542
 494 live in brackish waters. Finally, all freshwater gas- 543
 495 trotrichs are influenced by the characteristics of the 544
 496 water column, substrate, and aquatic vegetation. 545

497 Most freshwater chaetonotidans are epibenthic or 546
 498 periphytic in oxygenated habitats, and more abundant 547
 499 in eutrophic, standing waters (see Nesteruk, 2017 and 548
 500 references therein). The epibenthic community is 549
 501 generally more diverse and is dominated by eurytopic 550
 502 species of the genera *Chaetonotus*, *Lepidodermella*, 551
 503 *Heterolepidoderma*, and *Ichthydium*, whereas epi- 552
 504 phytic assemblages also include semiplanktonic 553
 505 species of Dasydytidae and Neogosseidae (Nesteruk, 554
 506 2000; Minowa & Garraffoni, 2017). Sandy sediments 555
 507 of lentic and running waters host all four freshwater 556
 508 species of Macrodasyida, but few species of Chaeto- 557
 509 notida (see Balsamo et al., 2014). Trophic levels and 558
 510 zonality of water bodies also influence the diversity 559
 511 and density of gastrotrich populations. Water bodies 560
 512 with a clear zonality provide a higher habitat diversity 561
 513 and consequently have a richer and more abundant 562
 514 fauna, especially in the littoral zone (Kisielewski, 563
 515 1981; Nesteruk, 2004b, 2005). Compositional differ- 564
 516 ences also exist between the sublittoral and the deep 565
 517 zone (Nesteruk, 1996b, 2004b). Alpha-mesotrophic 566
 518 waters are 26–45% richer in species than waters with a 567
 519 lower trophic level (Nesteruk, 1996b, 2004a). The few 568
 520 semiplanktonic or planktonic species preferentially 569
 521 live in eutrophic ponds, *Sphagnum* bogs, and transi- 570
 522 tional peat bogs, which appear to have the highest 571
 523 species richness, independent from altitude, vegeta- 572
 524 tion, and trophic level (Kisielewski, 1981, 1986, 1991; 573
 525 Balsamo, 1982; Balsamo & Todaro, 1995). In lotic 574
 526 habitats, gastrotrichs are mostly present where the 575
 527 water current is slower, such as vegetated river banks, 576
 528 bends of the water course, and in small streams 577
 529 (Kisielewski & Kisielewska, 1986; Kisielewski, 578
 530 1991). A few interstitial species have been reported 579
 531 from sediments of springs, rivers, and streams (Ricci 580
 532 & Balsamo, 2000; Nesteruk, 2008; Garraffoni et al., 581
 533 2017). Most gastrotrich species are able to colonize 582
 534 more than a single habitat and can migrate between the 583
 535 epibenthos, periphyton, and interstitial. 584

536 Very few studies specifically focus on the influence 585
 537 of abiotic variables on the occurrence and abundance 586

of freshwater microturbellarians. Kolasa (2002) pro- 538
 vides a brief overview on general preferences and 539
 tolerance ranges of several abiotic parameters, but 540
 only for few species tolerance ranges for temperature, 541
 oxygen, water level, oxygen, pH, and calcium are 542
 known (Heitkamp, 1982). Most species have an 543
 optimal temperature range for reproduction and pop- 544
 ulation growth to occur and temperature can have a 545
 significant influence on hatching and on the generation 546
 time (Heitkamp, 1988; Sayre & Wergin, 1994; 547
 Dumont et al., 2014). Some species are stenotherm, 548
 while others are eurytherm. Microturbellarians require 549
 oxygenated layers of water and sediment. Species that 550
 live in substrates of well-oxygenated, fast-running 551
 streams are particularly sensitive to low oxygen 552
 concentrations (Kolasa, 1983). A small number of 553
 freshwater rhabdocoels are euryhaline and can also be 554
 found in brackish water habitats (Ax, 2008). However, 555
 most microturbellarians that occur in brackish water 556
 are euryhaline marine species or genuine brackish 557
 water species that do not occur in freshwater habitats. 558
 Granulometry of freshwater sediments also influences 559
 species composition and occurrence. Kolasa et al. 560
 (1987) found higher species richness and abundance in 561
 stream sediments with a grain size of 0.4–0.7 mm, 562
 compared to a low species richness and abundance for 563
 small stones or large gravel. Young (1973) found that 564
 calcium-rich and calcium-poor lakes each have their 565
 specific species of microturbellarians, but also share a 566
 number of species. 567

568 Ecological surveys of microturbellarians associated 569
 with different freshwater habitats are mostly limited to 570
 older studies from Central and Southeastern Europe 571
 (e.g., An der Lan, 1939, 1962, 1967; Mack-Fira, 1974; 572
 Kolasa, 1979; Schwank, 1981a, b, 1982a, b). More 573
 recent studies from South America and the Middle 574
 East provide valuable data on species richness and 575
 seasonal abundance of microturbellarians in perman- 576
 ent wetlands and temporary pools (Eitam et al., 2004; 577
 Braccini & Leal-Zanchet, 2013). Microturbellarians 578
 are found in almost all types of lentic and lotic 579
 freshwater habitats. In addition, they also occur in 580
 limnoterrestrial habitats such as mosses and forest 581
 soils (Van Steenkiste et al., 2010; Houben et al., 2015). 582
 Many species are shared between habitats, but some 583
 species are associated with specific environments. 584
 Species numbers can be high in both lentic and lotic 585
 environments with up to 94 and 57 species recorded 586
 from a single stream and lake, respectively (Kolasa,

587 2000). In large lakes and reservoirs, species richness
 588 and abundance are significantly higher in sediments
 589 and aquatic vegetation in the littoral zone, but some
 590 species have also been found in the limnetic zone as
 591 part of the pelagic (Dumont et al., 2014). Permanent
 592 bodies of water are usually dominated by catenulids,
 593 macrostomids, prorhynchids, and rhabdocoels associ-
 594 ated with aquatic vegetation, plant roots, and sedi-
 595 ment, while temporary pools typically harbor species
 596 with drought resistant resting eggs, such as typhlo-
 597 planid and dalyelliid rhabdocoels (Artois et al., 2004;
 598 Eitam et al., 2004). Species compositions in lotic
 599 systems are highly variable. Mountain springs and fast
 600 flowing streams or rivers have unique hyporheic and
 601 psammophilic species or species associated with
 602 mosses and other vegetation along its course (Sch-
 603 wank, 1982a, b). The lower courses of rivers systems
 604 are inhabited by eurytopic species also found in lentic
 605 habitats. Assemblages of species are further enriched
 606 by species from habitats at the interface of lotic and
 607 lentic habitats, including limnoterrestrial, brackish
 608 water, and groundwater elements (Kolasa
 609 1983, 2000). A very detailed review on the distribution
 610 and abundance of microturbellarians in different
 611 aquatic habitats is given by Young (2001).

612 Spatial and temporal dynamics of rousphozoans' 613 populations

614 Spatial patterns and small-scale horizontal distribu-
 615 tions of rousphozoans are driven by abiotic and biotic
 616 factors such as the morphological features of the
 617 sediment, the heterogeneous distribution of organic
 618 matter, and bioturbation (Kisielewski, 1974–1999;
 619 Nesteruk, 1986–2017; Giere, 2009). This leads most
 620 meiofauna to aggregate in undisturbed sites or in areas
 621 richer in organic detritus, thus presenting a typical
 622 patchy distribution. Species composition can differ
 623 significantly between microhabitats, with adjoining
 624 patches of gravel, sand, plants, and organic debris
 625 having distinctive communities at the scale of
 626 centimeters.

627 The vertical distribution of gastrotrichs is highly
 628 related to grain size, oxygen concentration, presence
 629 and velocity of water flow, quantity of organic matter
 630 present in the interstitial water, predation pressure, as
 631 well as the tolerating abilities of different species
 632 (Palmer, 1990; Danielopol et al., 1997). The few
 633 interstitial freshwater species are mostly found in the

oxygenated upper 5 cm of the sediment, in which
 about 46–68% of the whole gastrotrich community has
 been reported. Some species (about 7–10% of the total
 gastrotrich fauna) can migrate down to 10–15 cm deep
 (Nesteruk, 1991). Only a few individuals have been
 found at 30–40 cm deep in lotic gravel habitats where
 wide interstices allow the penetration of oxygen
 (Schmid-Araya, 1997).

Temporal patterns of gastrotrich populations and
 influencing factors are not well known, especially in
 freshwater environments. Nesteruk (1986, 2007a,
 2017) reported decreased densities of some freshwater
 gastrotrich populations during summer and winter,
 probably related to the seasonal changes in oxygen
 concentration, water temperature, and food availabil-
 ity. Periods of drought and freezing in temperate zones
 strongly influence both the abundance and the struc-
 ture of communities. In tropical zones, gastrotrichs are
 present and even abundant in lentic waters throughout
 the year, with higher abundances during the rainy
 season. This change in abundance is probably linked to
 the sediment processes and recirculation of organic
 matter (Kisielewski, 1991; Zébazé Togouet et al.,
 2007; Strayer et al., 2010).

Very few studies present data on the vertical
 distribution of freshwater microturbellarians in the
 water column and in sediments. Although some lentic
 microturbellarians have been found in substrates at
 considerable depths of 20 m or more, most studies
 show that the largest numbers of species and individ-
 uals were found in the shallow waters up to 1 m of the
 littoral zone and then decline with depth. This decline
 in species richness and abundance is more pronounced
 in eutrophic lakes than in oligotrophic lakes (Young,
 2001; Kolasa, 2002). Some pelagic species of *Mesos-
 toma* follow the diurnal vertical migration of their prey
 in the water column, rising to the surface at night to
 feed on cladocerans and copepods (Rocha et al., 1990).
 Psammic stream-dwelling microturbellarians are most
 abundant at 20–40 cm deep inside gravel (Schmid-
 Araya, 1997). Species richness and abundance are,
 however, mostly a function of the presence of varied
 microhabitats. Studies on seasonal abundances of
 freshwater microturbellarians give a mixed image. In
 Europe and Southern Brazil, different species have
 different seasonal abundance peaks influencing com-
 munity compositions throughout the year (Young,
 2001; Braccini & Leal-Zanchet, 2013). Seasonal
 occurrence and abundance of microturbellarians also

683 seem to vary according to geographic location and are
684 most likely linked to the influence of temperature,
685 food availability, droughts and floods, and several
686 other abiotic and biotic variables. The scarcity of
687 studies available on these temporal dynamics high-
688 lights the need for more research in different parts of
689 the world.

690 Trophic and biotic interactions

691 Very few studies on gastrotrichs deal with their trophic
692 ecology, interactions within or among species, com-
693 petition with and predation by other organisms, or
694 their symbionts and parasites. Only a few qualitative
695 experimental studies on mixed cultures of freshwater
696 species have been done (d'Hondt, 1967; Bennett,
697 1975, 1979). The primary food seems to be bacteria
698 and the particulate organic matter on the sediment
699 surface, in interstitial spaces, and on the microbial
700 biofilm covering the substrate. Microalgae and other
701 protists probably supply some nutrients, but may not
702 be essential (Packard, 1936; Brunson, 1949). As the
703 interstitial environment is dominated by viscous
704 forces, all prey capture devices must be adapted to
705 overcome the functional challenge of feeding at very
706 low Reynolds numbers. Food uptake and transport are
707 therefore dependent on two important factors: the
708 entrance to the pharynx (mouth) and conductance of
709 the pharyngeal pump. Among meiofauna, only two
710 taxa rely exclusively on suction for prey capture,
711 nematodes and gastrotrichs (Ruppert, 1982). Both taxa
712 have near-identical foreguts (e.g., terminal mouth,
713 myoepithelial pharynx, triradiate lumen), yet differ in
714 pharyngeal ultrastructure. Nematodes have strictly
715 monosarcomeral pharynges that generate strong but
716 slow contraction. Consequently, nematodes evolved to
717 feed on different prey through selection on buccal size,
718 armature, muscle supply, and pharynx shape (Munn &
719 Munn, 2010). Alternatively, gastrotrichs have 1–12
720 sarcomeres/myofilament/species (Ruppert, 1982).
721 More sarcomeres should translate into greater speed
722 of contraction but with lower force; hence, different
723 lineages have made an evolutionary tradeoff of force
724 for speed (or speed for force), depending on ancestry.
725 An exploration of these tradeoffs should be carried out
726 by combining molecular diet analysis of selected
727 species whose diet is already partially known (either
728 by diagnostic PCR or by parallel sequencing—see
729 Rubbmark et al., 2019, for comparative review) with a

careful examination of pharynx structure by transmis-
sion electron microscopy and confocal laser scanning
microscopy. We predict that species with monosar-
comeral pharynges will be biofilm feeders, whereas
species with multisarcomeral pharynges will feed
primarily on eukaryotes. These studies should deter-
mine if gastrotrichs form feeding guilds akin to those
in nematodes (Hochberg, pers. comm.).

Both freshwater and marine gastrotrichs seem to
have chemotactic abilities to discriminate between
different bacterial strains (Gray & Johnson, 1970).
Sporadic observations in laboratory cultures did not
show apparent reciprocal interactions with conspecific
individuals (Banchetti & Ricci, 1998). Gastrotricha
certainly compete with other meiofaunal organisms in
feeding on bacteria, protists, biofilm, and organic
detritus. Large protists, cnidarians, flatworms, poly-
chaetes, and larvae of Diptera have been reported as
natural predators of Gastrotricha (Strayer & Hummon,
1991; d'Hondt, pers. comm.). The heliozoon *Acti-
nophrys sol* Ehrenberg, 1830 and the amoebozoan
Amoeba spumosa Grüber, 1885 were directly observed
feeding on freshwater chaetonotids, both solitarily and
cooperatively in samples collected in nature and kept
under laboratory conditions (Brunson, 1949; Bovee &
Cordell, 1971). Escape mechanisms of Gastrotricha lie
in sudden whole body contractions and rapid direction
changes in locomotion. Most chaetonotids, and
especially epibenthic or semiplanktonic species, also
have cuticular scales and/or long, sometimes movable
spines, and protective cephalic plates that act as
mechanical barriers against predators.

Individuals of freshwater Chaetonotida have been
observed containing putative sporozoans in their trunk
or euglenoids in their intestine, but it is not clear if
these are food items, endosymbionts or parasites
(Remane, 1936; Manylov, 1999; Kisielewska et al.,
2015). Nothing is known about possible epibiotic
associations between Gastrotricha and other taxa, like
those observed in other small aquatic micrometazoa
(i.e., Rotifera, Nematoda) (Bulut & Saler, 2017).

The diet of microturbellarians ranges from ciliary-
assisted feeding on bacteria and algae (Catenulida) to
(obligate?) diatomivory (some Macrostromorpha and
Rhabdoceola) and carnivory on other meiofauna and
the larvae of macroinvertebrates (see Watzin,
1983, 1986; Giere, 2009). Catenulids have a disten-
sible mouth to engulf food and transport it to the
pharynx simplex through large cilia around the mouth

779 opening. A few species in the catenulid genus
780 *Paracatenula* are mouthless and maintain symbiotic
781 bacteria in the gut (Dirks et al., 2011, 2012). Other
782 microturbellarians use their muscular pharynx for the
783 capture and uptake of prey items. The pharynx can be
784 distended to capture and ingest prey as a whole
785 (Stenostomidae, Dalyelliidae) or protruded to breach
786 the body wall of larger prey and suck up prey fluids
787 and tissues (Typhloplanidae, Proseriata). Kalyp-
788 torhynchs use their anterior proboscis to capture and
789 possibly envenomate prey and immobilize it while
790 positioning their pharynx. Some flatworms, such as
791 prorrhynchids and *Gyratrix hermaphroditus* Ehren-
792 berg, 1831, use their stylet to stab prey.

793 Feeding strategies of freshwater microturbellarians 793
794 include mucus trapping, active searching, ambush 794
795 predation, the use of toxins, and group foraging 795
796 (Young, 2001; De Roeck et al., 2005; Dumont et al., 796
797 2014), but comprehensive data on diet composition 797
798 and prey selection are very limited compared to 798
799 marine and brackish water microturbellarians (Wat- 799
800 zin, 1985; Reise, 1988; Menn & Armonies, 1999). 800
801 Diagnostic PCR was used to reconstruct the diet in 801
802 individual marine flatworm species (Maghsoud et al., 802
803 2014; Fig. 5), and could also prove valuable for 803
804 freshwater microturbellarians. One recent study shows 804
805 acquired prey selection of toxic and non-toxic ciliates 805
806 by the catenulid *Stenostomum sphagnetorum* Luther, 806

Table 4 Feeding guilds in flatworms based in part on pharyngeal structure (from Bilio, 1967; Straarup, 1970)

Taxon	Pharynx type ¹	Ex. FW Genera	Ex. Prey ^{2,3}	Guild
Catenulida	Simplex, ciliated lumen, ventral ciliated “mustache”	<i>Catenula</i> , <i>Suomina</i>	Unicellular eukaryotes; bacteria?	Ciliary sweep
Catenulida	Simplex, barrel-shaped	<i>Stenostomum</i>	Ciliates, Rotifers, other flatworms	Suction, holozoic ^{4,5}
Macrostomorpha	Simplex	<i>Macrostomum</i>	Diatoms, nematodes, juvenile mussels, cladocerans	Cilio-muscular, holozoic
Macrostomorpha	Simplex	<i>Microstomum</i>	Diatoms, <i>Hydra</i> tentacles, other FW	Cilio-muscular, holozoic
Proseriata	Plicate, wreath-shaped to tubular	<i>Coelogygnopora</i> ,	Oligochaetes, copepods, carrion	Suction, Holozoic or sucking prey contents
Rhabdocoela	Bulbous, rosulate	<i>Castrada</i>	Diatoms, green algae, rotifers, oligochaetes, cladocerans, copepods, insect larvae, other FW	Suction, holozoic or sucking prey contents
Rhabdocoela	Bulbous, doliiform	<i>Gieysztorja</i>	Diatoms, green algae, rotifers, nematodes, oligochaetes, other flatworms	Suction, holozoic

References: ¹Rieger et al. (1991); ²Kolasa & Tyler (2010), ³Young (2001), ⁴ Nuttycombe & Waters (1935), ⁵Smith & Davis (unpublished)

1960; this behavior was lost after asexual reproduction (Buonanno, 2011). Freshwater microturbellarians can reach high densities and studies have shown that predation by species of *Mesostoma* and *Phaenocora* can influence the population dynamics of zooplankton or benthic communities seasonally (Young, 1977; De Roeck et al., 2005; Dumont et al., 2014). Larger microturbellarians that feed on mosquito larvae have therefore been proposed as biological control agents (Tranchida et al., 2009). Feeding guilds based in part on pharyngeal structure have been hypothesized in flatworms (e.g., Bilio, 1967; Straarup, 1970; Table 4). Species of *Macrostomum* may be specialist feeders on diatoms or, alternatively, take any relatively slow-moving prey small enough to swallow, including juvenile mussels and cladocerans (Delp, 2002). Proseriata with a ventrally directed plicate pharynx and rhabdocoels with a bulbous rosulate pharynx often use that to suck out prey contents (Jennings, 1974b; own observations). Rhabdocoels with an anterior barrel-shaped (doliiform) pharynx often suddenly dilate the pharynx, suck in, and swallow fast-moving prey whole (Bilio, 1967). Rapidly contracting radial muscles could play a role in overcoming viscous forces and quickly sucking in smaller prey. This mechanism is used to capture swimming prey by some members of

the genus *Stenostomum* (Nuttycombe & Waters, 1935) and confocal microscopy of the head region in *Stenostomum virginianum* Nuttycombe, 1931 shows pseudostriation of the radial musculature in the pharynx—an arrangement that is predicted to increase contraction velocity (Smith & Davis, unpublished). Interestingly, pseudostriation has also been observed in the pharyngeal radial muscles of a Prolecithophoran (Rieger et al., 1991). Additionally, congenics occurring in the same biotope (e.g., *Catenula lemnae* Duges, 1832 and *Catenula confusa* Nuttycombe, 1956) might have different diets that are reflected in the structure of their pharynges—for instance, size-selection between unicellular algae vs bacteria. In summary, one would expect to find both convergent and divergent adaptations across the different pharynx types—adaptations that depend in part on prey mobility, and in part on prey size (e.g., sucking out the body contents of oligochaetes and amphipods vs swallowing smaller prey whole). However, there appear to be no published studies directed at understanding the biomechanics of the pharynx in microturbellarians.

Microturbellarians are also eaten by other invertebrates, small vertebrates, and even protists. Defensive behavior such as the release of mucous to escape from predatory ciliates has been observed (Buonanno,

859 2009) and rhabdites have long been suggested to be
 860 defensive, whether or not their primary role is mucus
 861 production for ciliary gliding (Rieger et al., 1991).
 862 Both intra- and interspecific predation by other
 863 microturbellarians have also been recorded (Young,
 864 2001; own observations). Although the extent and
 865 impact of predation on microturbellarian populations
 866 have not been assessed in detail, predator exclusion
 867 did not produce the expected increase in platy-
 868 helminthes, suggesting that predation does not regu-
 869 late flatworm populations except under specialized
 870 circumstances (Reise, 1979; Giere, 2009).

871 Freshwater microturbellarians, and then predomi-
 872 nantly rhabdocoels, can be both ectosymbionts on
 873 other freshwater animals and hosts for other organ-
 874 isms. Temnocephalids are small freshwater epibionts
 875 on macroinvertebrates and turtles. They prey on other
 876 co-symbiotic organisms and feed opportunistically on
 877 particles of the host's food. The dalyelliid *Varsoviella*
 878 *kozminskii* Gięsztor & Wiszniewski, 1947 lives on
 879 the gills of freshwater gammarids (Gięsztor &
 880 Wiszniewski, 1947). A number of freshwater species
 881 in the genera *Castrada*, *Dalyellia*, *Gięsztoria*,
 882 *Phaenocora*, and *Typhloplana* harbor endosymbiotic
 883 chlorophytes. Little is known about this symbiosis, but
 884 studies on *Phaenocora typhlops* (Vejdovsky, 1880),
 885 *Dalyellia viridis* (Shaw, 1791), and *Typhloplana*
 886 *viridata* (Abildgaard, 1789) suggest that worms could
 887 benefit from the photosynthate and oxygen produced
 888 by the algae (Young, 2001 and references therein).
 889 Kleptoplasty, a form of endosymbiosis where only the
 890 algal plastids are sequestered and retained, has
 891 recently been observed in marine and brackish water
 892 rhabdocoels (Van Steenkiste et al., 2019). Species of
 893 the genus *Microstomum* often retain nematocysts from
 894 digested *Hydra* tentacles as kleptocnids (Fig. 3f,
 895 arrows). Parasites of freshwater microturbellarians
 896 have occasionally been recorded in older taxonomic
 897 literature, but very few studies characterize the
 898 observed parasites in detail. Most of these parasites
 899 are protists, including apicomplexans, microsporidi-
 900 ans, ciliates, and euglenozoans. Only a few records
 901 mention metazoan parasites such as nematodes or
 902 neodermatan flatworms (for details, see Young, 2001
 903 and references therein). It is noteworthy that the last
 904 comprehensive review of microturbellarians as para-
 905 sites and hosts was published over 100 years ago (von
 906 Graff, 1903), and less comprehensive modern sum-
 907 maries are available (Jennings, 1971, 1974a, 1977).

Life strategies

908
 909 Gastrotrichs have various reproductive modalities.
 910 While marine Macrodasyida are hermaphrodite with
 911 cross-fertilization, freshwater Chaetonotida generally
 912 reproduce by thelytokous parthenogenesis. As a
 913 consequence, freshwater populations can start from
 914 any single individual. Many freshwater species can
 915 also produce resting eggs that can withstand environ-
 916 mental adverse conditions and act as dispersal propa-
 917 gules. The factors triggering the production and the
 918 hatching of the resting eggs are not yet known.
 919 Parthenogenesis, resting eggs, and short life cycles
 920 allow gastrotrichs to survive extreme variations in
 921 environmental conditions (e.g., droughts, floods) and
 922 colonize challenging habitats such as lotic sediments
 923 (Ricci & Balsamo, 2000), caves (Vandel, 1964;
 924 Renaud-Mornant, 1986; Kolicka et al., 2017), high
 925 mountain biotopes (Baumann, 1910; Tonolli &
 926 Tonolli, 1951; Gadea, 1988), hot springs (De Guerne,
 927 1888), and deep crater lakes (Barrois, 1896; R.
 928 Schabetsberger, unpublished data). In addition, indi-
 929 viduals might also be able to survive critical condi-
 930 tions by migrating deeper into the sediment (Nesteruk,
 931 2007c).

932 Laboratory tests have evidenced the existence of a
 933 long postparthenogenic phase with production of
 934 aberrant spermatozoa in Chaetonotida. This suggests
 935 a possible amphimictic reproduction, and thus the
 936 existence of two successive reproductive modalities in
 937 a single lifespan. Such a biphasic reproduction strat-
 938 egy would allow for a quick increase in population
 939 numbers through apomictic parthenogenesis followed
 940 by the introduction of genetic variation through cross-
 941 fertilization (Balsamo, 1992; Hummon & Hummon,
 942 1992).

943 Microturbellarians are hermaphrodites and display
 944 both sexual (cross- and self-fertilization) and asexual
 945 (paratomy) modes of reproduction (Kolasa, 2000).
 946 Catenulids and some macrostomids (e.g., *Microsto-*
 947 *mum*) reproduce asexually, although sexual reproduc-
 948 tion can also occur. Most other freshwater
 949 microturbellarians reproduce by internal cross-fertil-
 950 ization, either by mutual copulation or sometimes by
 951 hypodermic impregnation. Self-fertilization is rare
 952 and has only been observed in a few species (Young,
 953 2001).

954 Life histories of freshwater microturbellarians are
 955 not well understood and only known for a handful of

species from temperate regions (Cox & Young, 1974; Heitkamp, 1988). Microturbellarians can produce both subitaneous (non-resting) eggs for rapid population growth during their active phase and dormant resting eggs/cocoons enclosed by a thicker, more resistant shell at the end of their active phase to overcome periods of high/low temperature, water level changes, or desiccation (Young, 2001). Life cycles are conditioned by seasonal cycles and droughts or flooding events. As such, many species have flexible life cycles depending on geographic location and habitat. Annual species are active year-round and restricted to permanent water bodies. Reproduction appears in one or more generations throughout the year, often during a specific season and influenced by temperature, food, and the presence of water. Seasonal species only appear in one or more seasons which often overlap with periods of vegetation growth and/or phyto- and zooplankton blooms.

A comparative summary of modes of reproduction of freshwater gastrotrichs and microturbellarians is reported in Table 5.

Global diversity and distribution

The majority of freshwater gastrotrichs are Chaetonotida, with about 350 species in 5 families and 24 genera (72% of total chaetonotidan species). Only four species of Macrodasysida, in one family and one genus (except one species *incertae sedis*), occur in fresh waters (Kisielewski, 1987; Kånneby & Kirk, 2017; Garraffoni et al., 2019). Diversity of freshwater Gastrotricha in different geographic areas is not as well known as that of marine species, and available data are quite heterogeneous. Most research has been carried out in Europe and the Americas. Data on geographic distribution are usually limited to the

sampling sites, especially in older literature, and occasionally include some ecological data (see Balsamo et al., 2014 for previous references). This insufficient knowledge is a direct consequence of technical problems that are common to all soft-bodied meiofaunal animals and concern their collecting and handling, but also to the particular focus of most studies on the epibenthic and periphytic species from standing water bodies. Moreover, the taxonomy—especially of the order Chaetonotida—is still unstable because of the intraspecific variability of many species, the scarcity of diagnostic data in old descriptions, and the increasing evidence of the existence of cryptic species in widespread nominal species (Kieneke et al., 2012; Kånneby et al., 2012, 2013). In Europe, the continent studied most thoroughly, about 250 species have been identified and some countries have been the object of regional ‘faunas’ (Balsamo, 1983; Balsamo & Tongiorgi, 1995; Balsamo et al., 2014 for global references). Of course the effect of sampling effort should be considered in advancing possible scenarios of the global diversity and distribution of the phylum, also because large areas in most other parts of the world have not been explored yet (Balsamo et al., 2008, 2014; Fontaneto et al., 2012). Three out of four species of freshwater Macrodasysida (fam. Redudasyidae) are reported from the Americas (Fig. 6), while the fourth species (*Marinellina flagellata* Ruttner-Kolisko, 1955, *incertae sedis*) is known from Austria (Ruttner-Kolisko, 1955; Schmid-Araya & Schmid, 1995). As for Chaetonotida, three of the five freshwater families, Dasydytidae, Neogosseidae, and especially Chaetonotidae, appear to be cosmopolitan, and most genera and species have been recorded in at least two continents, especially in tropical areas (Figs. 7, 8). Representatives of the rare family Dichaeturidae have occasionally been found in a few European localities and a single Japanese site. Each of

Table 5 A comparative summary of modes of reproduction of freshwater gastrotrichs (M, Macrodasysida; C, Chaetonotida) and microturbellarians

	Gastrotrichs	Microturbellarians
Asexual reproduction	Thelytokous parthenogenesis in M and C	Paratomy (Catenulida, <i>Microstomum</i>)
Sexual condition	Female only	Hermaphroditic only
Sexual reproduction	Suspected postparthenogenic sexual phase in C	Cross- and self-fertilization
Resting stages	Resting eggs	Resting eggs/cocoons

Fig. 6 A freshwater genus of Macrotrichidae, *Redudasys*. **a** Lateral view of the head showing the diagnostic single adhesive tube (SEM); **b** detail of the caudal body end with four adhesive tubes (DIC microscopy)

the two species of the family Proichthyidiidae has only been recorded once in their respective type localities in South America and Asia (see Balsamo et al., 2014 for detailed references). About half of the freshwater genera have an intercontinental distribution; about 1/3 of the European species and 1/3–1/2 of the South American species appear to be cosmopolitan. Tropical areas generally have a high diversity of genera and species. Brazil in particular has many endemic genera, some of which are only known from a single site in Amazonia (e.g., *Undula* in the chaetonotid subfamily Undulinae). There are also numerous other records of species from only one country and often from only one site, but knowledge on gastrotrich diversity in surrounding countries and regions is not sufficient to

define these species as endemic (Balsamo et al., 2014; Garraffoni & Balsamo, 2017).

An update of the situation reported in Balsamo et al. (2008) highlights the increase in the number of new freshwater species of gastrotrichs recently described, mainly from the Palearctic, but also from the Neotropic and Nearctic (Balsamo et al. 2019; Todaro et al., 2019) (Table 6a; Fig. 9a). This increase is not only related to an increased sampling effort, but also to investigations in environments not yet explored such as Arctic waters and artificial water bodies (greenhouses) (Kolicka et al., 2018; Kolicka, 2019 and references therein).

Global species numbers in the different groups of freshwater microturbellarians amount to the following numbers: Catenulida (95 species), Macrostromorpha (118 species), Prorhynchida (31 species), Proseriata (12 species), Rhabdozoela (739 species), Proleptothorax (20 species), and Bothrioplanida (2 species) (Table 6b). The majority of freshwater species belong to three groups within the rhabdozoel clade Limnotyphloplanida: Temnocephalida (160 species), Dalyelliidae (174 species), and Typhloplanidae (271 species). Knowledge on the diversity and distribution of freshwater microturbellarians in different parts of the world is relatively scarce and, as for most other freshwater meiofauna, reflects the historical efforts and geographical work area of taxonomists rather than actual microturbellarian diversity and distribution. Table 6b and Fig. 9b summarize species numbers for microturbellarians in each biogeographic zone. These numbers are the most current update since the census of freshwater turbellarians in Schockaert et al. (2008). Increased species numbers and distribution records for the Palearctic can largely be attributed to increased taxon sampling of catenulids (Larsson & Willems, 2010), macrostromids (Rogozin, 2012), rhabdozoels (Rogozin, 2011, 2017; Van Steenkiste et al., 2011b; Korgina, 2014; Timoshkin et al., 2014; Houben et al., 2015), and proseriates (Timoshkin et al., 2010), and to the recognition of cryptic species within *Microstromum* (Atherton & Jondelius, 2018). Species numbers and records in the Nearctic have increased slightly due to recent surveys of rhabdozoels in Canada and the USA (Van Steenkiste et al., 2011a; Houben et al., 2014). The largest increase in species numbers and records can be found in the Neotropical, Oriental, and Australian regions thanks to recent studies describing and recording several dozens of rhabdozoels and

Fig. 8 A semiplanktonic genus of Chaetonotida, *Neogossea*. **a** ventral view; **b** detail of cuticular scales and spines (SEM)

1093 macrostomids in South America (e.g., Adami et al.,
1094 2012; Martínez-Aquino et al., 2014; Braccini et al.,
1095 2016), Southern China (Sun et al., 2015; Lin et al.,
1096 2017), and India and Australia (e.g., Van Steenkiste
1097 et al., 2012). Only a marginal increase or status quo in
1098 species records are shown for the Afrotropical, Pacific,
1099 and Antarctic regions, where almost no or very few
1100 studies on microturbellarians have been conducted in
1101 the past decades. While global species numbers have
1102 increased with over 16% in the last 12 years, biodi-
1103 versity surveys of microturbellarians in some of the
1104 world's largest and most diverse freshwater systems,
1105 such as the Pantanal or the basins of the Amazon,
1106 Congo, and Ganges–Brahmaputra rivers, are still very
1107 limited or non-existent. Several freshwater habitats,
1108 such as limnoterrestrial habitats are seldom sampled
1109 and could contain a hidden reservoir of microturbel-
1110 larian diversity (Van Steenkiste et al., 2010; Houben
1111 et al., 2015). Phreatic aquifers or peat swamp forests
1112 remain unexplored altogether. As such, our freshwater
1113 microturbellarian census clearly shows a large poten-
1114 tial for species discovery in freshwater habitats around
1115 the world. Even in the most intensely sampled

biogeographical regions, including the Palearctic, 1116
Nearctic, and Neotropics, vast areas and many habitats 1117
are still to be surveyed. 1118

As a result of the paucity of data on species 1119
diversity in many regions, biogeographic patterns for 1120
freshwater microturbellarians are hard to infer. While 1121
the majority of species have so far only been recorded 1122
from one biogeographic region (“endemic species” in 1123
Table 6b), some nominal species of catenulids (e.g., 1124
Stenostomum leucops (Duges, 1828)), macrostomids 1125
(e.g., *Microstomum lineare* (Müller, 1773)), and 1126
rhabdocoels (e.g., *Gyratrix hermaphroditus*) seem to 1127
have cosmopolitan distributions. Others are wide- 1128
spread, but confined to one or two biogeographic 1129
regions. For instance, several nominal species of 1130
dalyelliids (e.g., *Microdalyellia armigera* (Schmidt, 1131
1861), *Gieystoria cuspidata* (Schmidt, 1861), *Cast- 1132
rella truncata* (Abildgaard, 1789)) have a Holarctic 1133
distribution. One hypothesis is that the widespread 1134
distribution of micro-organisms could be the result of 1135
long-distance dispersal by long-term resistant dormant 1136
stages and the ability to colonize and reproduce 1137
quickly (Fontaneto, 2019). In addition, some of these 1138
widespread nominal species could be complexes of 1139
closely related species, the so-called (pseudo)cryptic 1140
species. This has been demonstrated in both marine 1141
(Scarpa et al., 2016; Van Steenkiste et al., 2018) and 1142
freshwater (Atherton & Jondelius, 2018) microturbel- 1143
larians, where several nominal species are now 1144
considered complexes of different species. 1145

On a superspecific level, distribution patterns of 1146
freshwater microturbellarians are even harder to 1147
untangle. Most genera have representatives in differ- 1148
ent biogeographical regions. Some genera or species 1149
groups seem confined to certain biogeographical areas 1150
and their distribution could possibly be explained by a 1151
combination of geological events and dispersal. 1152

Perspectives 1153

The majority of studies on routhozoans are mostly 1154
conducted by researchers in Europe and the Americas. 1155
Programs for taxonomic capacity building in devel- 1156
oping countries could benefit biodiversity surveys of 1157
freshwater meiofauna in the vastly undersampled but 1158
biodiverse freshwater ecosystems of Africa, Southeast 1159
Asia, and the Americas. These regions might be of 1160
crucial importance for a more realistic biodiversity 1161

Table 6 Current species numbers for a. Gastrotricha and b. microturbellaria in different biogeographical regions of the world, including numbers of endemic species per region and species numbers from the 2008 census of Balsamo et al. (2008) and Schockaert et al. (2008) for comparison

1162 estimation of microturbellarian and gastrotrich species
1163 diversity, but are at risk because of rapid habitat
1164 destruction and climate change. Wide-ranging Euro-
1165 pean research programs on the freshwater animal
1166 biodiversity have been carried out in the past years
1167 (2000–2008) leading to the compilation of European
1168 and global databases of the known biodiversity at the
1169 time (Fauna.Europaea Project, see de Jong, 2014;
1170 FADA Freshwater Animal Diversity Assessment
1171 Project, see Balsamo et al., 2008). Increased species
1172 discovery should be a concerted effort with expanding
1173 and updating databases that consolidate existing and
1174 new taxonomic and biogeographic data. An important
1175 first step would be the development of regularly
1176 updated identification keys for freshwater rousho-
1177 zoans. This could be part of a broader effort on
1178 freshwater meiofauna analogous to current efforts for
1179 marine meiofauna (Schmidt-Rhaesa, 2020). To accel-
1180 erate biodiversity surveys of roushozoans, protocols
1181 for animal collection, vouchering, DNA extraction,
1182 DNA barcode marker selection, amplification, and
1183 sequencing should be adjusted to the upcoming and
1184 promising third-generation sequencing techniques
1185 (e.g., Nanopore).

1186 A large impediment for future research on taxon-
1187 omy, biogeography, and phylogeny of Roushozoa
1188 (and all other Metazoa for that matter) is the imple-
1189 mentation of the Nagoya Protocol (NP). Since October
1190 2014, NP regulates all access to, and benefit sharing of,
1191 genetic resources worldwide. The protocol was
1192 designed to ensure fair use of countries' genetic
1193 resources, including the use of traditional knowledge.
1194 However, as logical and fair such legislation might

1195 seem, many concerns have been uttered (Deplazes-
1196 Zemp et al., 2018, and references therein). Whereas
1197 the NP and resulting legislation is needed to counter
1198 biopiracy and ensure that countries are not robbed of
1199 their economically valuable biological and genetic
1200 resources, it has devastating side effects on (descrip-
1201 tive) fundamental research. Without any doubt, the NP
1202 will significantly slow down taxonomic and other
1203 biodiversity studies just in an era in which such
1204 projects are much needed. For instance, in our daily
1205 work on microturbellarians, specimens are exchanged
1206 between researchers on a very regular base, in several
1207 cases involving colleagues from developing countries
1208 with whom we try to build up a structural collabora-
1209 tion. Because of the regulations of the NP, such
1210 exchange of material, indispensable for fruitful joint
1211 scientific activities, is hampered. The administrative
1212 workload will discourage international collaboration
1213 between researchers and will cause (and is already
1214 causing) a bias towards research in countries that did
1215 not ratify the NP. Moreover, for many biologists and
1216 institutes, it is not entirely clear (yet) what procedures
1217 should be followed in practice. We can only hope that
1218 the regulations of the NP will be revised in the future
1219 to ensure that at least the much-needed fundamental,
1220 non-profit research can continue smoothly.

1221 Dispersal abilities of freshwater gastrotrichs and
1222 microturbellarians and the relationship between dis-
1223 persal and distribution have not been specifically
1224 investigated so far. The small size of gastrotrichs and
1225 microturbellarians and the absence of planktonic
1226 stages limit active dispersal of live individuals to
1227 short distances. Wind, running water, and more mobile

Fig. 9 Current species numbers for **a.** Gastrotricha and **b.** microturbellarians in different biogeographical regions of the world (black numbers and circles), including numbers of endemic species per region (light grey numbers and circles)

and numbers of species shared between regions (dark grey numbers and lines). *PA* Palearctic, *NA* Nearctic, *NT* Neotropical, *AT* Afrotropical, *OL* Oriental, *AU* Australian, *PAC* Pacific, *ANT* Antarctic

1228 animal vectors have all been proposed as passive long-
 1229 distance dispersal vectors for long-term desiccation-
 1230 resistant eggs or cocoons of rouphozoans (Gerlach,

1231 1977; Hagerman & Rieger, 1980; Young, 2001; 1231
 1232 Vanschoenwinkel et al., 2008, 2009; Viana et al., 1232
 1233 2016). Human-mediated dispersal (aquaculture, 1233

- 1234 ballast waters, etc.) of gastrotrichs, microturbellarians, 1283
 1235 and many other aquatic micro-invertebrates is likely, 1284
 1236 but has not yet been the subject of specific studies 1285
 1237 (Artois et al., 2011). Future studies focusing on the 1286
 1238 spatial connectivity and gene flow of freshwater 1287
 1239 gastrotrich and microturbellarian populations are 1288
 1240 highly needed to support these assumptions. Cerca 1289
 1241 et al. (2018) have stressed the importance of including 1290
 1242 ecological and life-history traits, evolutionary history 1291
 1243 and cryptic speciation, metapopulation dynamics, as 1292
 1244 well as considering vicariant events and (ancient) 1293
 1245 dispersal routes on different geographic and temporal 1294
 1246 scales to explain current-day distribution of marine 1295
 1247 meiofauna. These are all important considerations to 1296
 1248 also elucidate recent distribution patterns of freshwa- 1297
 1249 ter gastrotrichs and microturbellarians. 1298
 1250 The task of untangling hidden diversity, spatial 1299
 1251 connectivity, and trophic networks in Rousphozoa will 1300
 1252 certainly fall to molecular methods. Metagenetic, 1301
 1253 genomic, and transcriptomic data—when combined 1302
 1254 and integrated with morphological and ecological 1303
 1255 data—can also provide new insights into additional 1304
 1256 properties and patterns such as niche differentiation, 1305
 1257 differential gene expression, genome duplication or 1306
 1258 reduction, character evolution, reproduction modes 1307
 1259 and traits related to sexual selection, origins of 1308
 1260 symbiotic interactions, co-evolution and host speci- 1309
 1261 ficity, nutritional strategies, and life cycle modifica- 1310
 1262 tions. The current lack of such integrated studies 1311
 1263 impedes our understanding on evolutionary processes 1312
 1264 within rousphozoans. Many closely related species of 1313
 1265 freshwater gastrotrichs and microturbellarians occur 1314
 1266 in sympatry suggesting some kind of ecological 1315
 1267 differentiation. However, non-ecological speciation 1316
 1268 in allopatry at some point in the past has been proposed 1317
 1269 for present-day sympatric organisms (Czekanski-Moir 1318
 1270 & Rundell, 2019). Species flocks of rhabdocoels in 1319
 1271 Lake Baikal are the product of spectacular speciation 1320
 1272 events, but the mechanisms behind these radiations are 1321
 1273 not known. Revealing these underlying processes 1322
 1274 remains challenging and will require holistic multi- 1323
 1275 evidence approaches employing new techniques in 1324
 1276 high-resolution microscopy and high-throughput 1325
 1277 sequencing. 1326
 1278 Finally, there is still a valuable role for functional 1327
 1279 morphology, specifically, studies with a biomechan- 1328
 1280 ical approach. From the original analysis of the role of 1329
 1281 connective tissue in soft-bodied worms (Clark & 1330
 1282 Cowey, 1958), and subsequent refinements applied to 1331
 soft-tissue extensible structures more generally (Kier, 1332
 2010), biomechanical studies in Rousphozoa are rare: 1333
 proboscis function in *Cheliplana* (Uyeno & Kier, 1334
 2010) and in Schizorhynchia more generally (Smith 1335
 et al., 2015), and dynamics of duo-gland adhesion in 1336
 marine microturbellaria (Wunderer et al., 2019). 1337
 Accordingly, additional studies directed at a better 1338
 understanding of rousphozoan biomechanics would 1339
 provide a much richer context for the evolutionary and 1340
 ecological work proposed above. 1341

Author Query Form

Please ensure you fill out your response to the queries raised below and return this form along with your corrections

Dear Author

During the process of typesetting your article, the following queries have arisen. Please check your typeset proof carefully against the queries listed below and mark the necessary changes either directly on the proof/online grid or in the 'Author's response' area provided below

Query	Details Required	Author's Response
AQ1	Please check whether the term 'diatomivory' is spelled correctly and amend if necessary.	
AQ2	Please check and confirm the layout of Table 1.	
AQ3	Please check and confirm all level section headings.
