# 16 Abstract

In the recent past engine knock emerged as one of the main limiting aspects for the achievement of higher efficiency targets in modern spark-ignition (SI) engines. To attain these requirements, engine operating points must be moved as close as possible to the onset of abnormal combustions, although the turbulent nature of flow field and SI combustion leads to possibly ample fluctuations between consecutive engine cycles. This forces engine designers to distance the target condition from its theoretical optimum in order to prevent abnormal combustion, which can potentially damage engine components because of few individual heavy-knocking cycles.

A statistically based RANS knock model is presented in this study, whose aim is the prediction not only of 24 the ensemble average knock occurrence, poorly meaningful in such a stochastic event, but also of a knock 25 probability. The model is based on look-up tables of autoignition times from detailed chemistry, coupled 26 with transport equations for the variance of mixture fraction and enthalpy. The transported perturbations 27 around the ensemble average value are based on variable gradients and on a local turbulent time scale. A 28 multi-variate cell-based Gaussian-PDF model is proposed for the unburnt mixture, resulting in a statistical 29 distribution for the in-cell reaction rate. An average knock precursor and its variance are independently 30 calculated and transported; this results in the prediction of an earliest knock probability preceding the 31 ensemble average knock onset, as confirmed by the experimental evidence. The proposed model estimates 32 not only the regions where the average knock is promoted, but also where and when the first knock is more 33 likely to be encountered. 34

The application of the model to a RANS simulation of a modern turbocharged direct injection (DI) SI engine with optical access is presented and the analysis of the knock statistical occurrence obtained by the proposed model adds an innovative contribution to overcome the limitation of consolidated "average knock" analyses

- 38 typical of a RANS approach.
- 39

# 40 Introduction

41 In the last decades several approaches were proposed to numerically predict and simulate the average engine

42 knock in the framework of RANS simulations. Their development was driven to meet the increasing

43 efficiency targets requested by legislation. Thermal efficiency and specific output power are raised to

44 unprecedented levels, in order both to reduce fuel consumption and pollutant emissions and to

45 simultaneously preserve the desired target performance levels.

Under high thermal loads abnormal combustion events are promoted, the most harmful of which is engine 46 knock. Knock is the consequence of the self-ignition of a portion of unburnt mixture ahead of the main 47 propagating flame front, and its occurrence is enhanced by the mentioned strategies, as outlined in [1]. Given 48 the need to operate as close as possible to the theoretical optimum of the regular combustion range [2] and 49 the simultaneous random nature of the turbulent combustion typical of internal combustion engines, the 50 occurrence of engine knock is a possibility that is always to be accounted for when the operating condition is 51 experimentally calibrated. To this aim, in-cylinder pressure is monitored in order to observe the random 52 presence of knocking events. This is assessed by the definition of knock indices, such as the commonly 53 adopted MAPO (Maximum Amplitude of Pressure Oscillations) or IMPO (Integral Modulus of Pressure 54 Oscillations) as widely surveyed by [3, 4, 5], as well as other indicators like the DKI (Dimensionless Knock 55 Indicator) [6] or the time-derivative of the in-cylinder pressure trace. Irrespectively of the chosen indicator, 56 an arbitrary threshold value is always present to discern between a soft and acceptable knock intensity and a 57 heavy and damaging knock level. Threshold values are part of engine manufacturer know-how and 58 standardized limits are not defined. 59

All the mentioned aspects motivate why a significant research effort was paid to knock prediction in the recent years. Quasi-dimensional and three-dimensional CFD models for average knock prediction were developed and validated against experiments by several research groups. Vancoillie and co-authors used a fuel-specific Arrhenius formulation for the reaction rate of methanol and ethanol fuels in [7], and the average ignition delay was used to integrate a knock precursor species. A similar modelling approach was used by Forte et al. [8] and Corti et al. in [9] for gasoline fuels.

However, the ensemble average approach to knock modelling through the use of RANS simulations suffers 66 of the inability to reproduce the intrinsically stochastic nature of knock; this is a strong limitation for this 67 type of models. The dramatic impact of cycle-to-cycle variability (CCV) on all the in-cylinder physical 68 processes, such as fuel-air mixing, combustion initiation and turbulent burn rate, motivates the adoption of 69 more refined approaches. In fact, since engine knock depends on all the preceding processes, it is itself a 70 typically stochastic and cycle-dependent phenomenon whose accurate prediction is therefore extremely 71 complex. A rigorous analysis of CCV can only be carried out through the use of Large-Eddy Simulation 72 73 (LES), where the largest flow structures are resolved allowing the simulation of flow unsteadiness deriving from large-scale turbulence. Despite the still demanding cost of this type of analyses, several promising 74 studies of this kind were presented in the recent years, such as the works by Robert et al. [10, 11]. They 75 showed that the simulated combustion CCV was able to replicate the degree on instability measured at the 76 test-bench for a premixed isooctane-air engine at several spark timings. Large-Eddy Simulation was used to 77 predict knock occurrence in a turbocharged GDI unit by the authors in previous studies [12, 13, 14], and the 78 cycle-dependent knock-signature well correlated with the outcomes from the experimental test-bench for 79 both Knock-Limited Spark Advance (KLSA) and for a knocking regime with an advanced spark-timing. 80 These examples showed the investigation insight made possible by LES and the possibility to explain 81 individual misfiring cycles or cycle-specific knocking events, thus allowing a direct comparison between 82 83 simulation results and engine test-bench output. However, the application of LES on production engines still suffers from the severe computational cost, preventing a full application in the design process of current 84 85 units.

In this context the definition of a new approach for knock modelling emerges as a necessary bridge between 86 the poorly representative RANS mean knock prediction and the relevant CPU effort of a multiple cycle LES 87 study. This is based on the RANS formalism for average quantities, combined with the use of transport 88 equations for variances of physical conditions, allowing to estimate a knock probability or a fraction of 89 knocking cycles. The statistical RANS knock model proposed in this paper relies on transport equations for 90 91 mixture fraction and enthalpy variances; detailed chemistry is used to calculate an accurate ignition delay of a gasoline surrogate model for the unburnt mixture. The variances of the variable are used as a basis of a 92 multi-variate Gaussian model of the unburnt fluid cell, from which information on both the average reaction 93 rate and its deviation are used to infer a presumed distribution of knocking events around the mean knock 94 onset. An innovative definition for a probability of knocking cycles is proposed based on the same statistical 95 basis deriving from the model equations, differently from what previously proposed by Linse et al. [15]. An 96

initial application of the PDF-knock model was presented by the authors in [16], and the application on a
 knock-limited turbocharged GDI engine successfully predicted 6% of knocking cycles while the ensemble

98 average realization was knock-safe. If a traditional RANS knock model was used, a knock-safe condition

- would have emerged, with no further information available on knock probability and lack of correlation with
- the experimental acquisitions. Conversely, the use of the presented PDF-knock model gave a quantitative
- 102 information regarding the presumed fraction of knocking cycles affecting the mean simulation for a given
- 103 operating condition, thus enhancing the meaning of a RANS simulation of knock with a typical test-bench
- acquisition dataset. This initial application motivated the development of the statistical knock model and the
- 105 application on a research single-cylinder engine presented in this paper.

In the next section the details of the knock model are presented, which is based on detailed chemistry 106 tabulation to accurately reproduce the local reaction rate. A statistically-based treatment accounting for 107 presumed turbulence-chemistry interaction is presented and transport equations for the local perturbation of 108 the thermal and mixing state are introduced. Finally, the derivation of the mean knock precursor and of its 109 variance are presented. The model is applied to an optically accessible GDI engine, and the knock prediction 110 given by the presented model is compared to the experimental outcomes in terms of frequency of knocking 111 cycles. A criterion is also proposed to correlate the results from the Probability Density Function (PDF) 112 based knock model with the number of knocking cycles, and the potentiality and the limitations of the 113

- 114 presented model are critically presented and discussed.
- 115

# 116 **Presumed-PDF Knock Model**

#### 117 Cell-Average Reaction Rate

The first step of the presented model is based on the calculation of a cell-wise average reaction rate. A procedure for the calculation of the autoignition (AI) delay is presented in [17, 18] and it is deputed to the

interpolation of a cell-specific delay time from a pre-calculated database of calculated delay times  $\tilde{\tau}$ . Multi-

dimensional interpolation is carried out considering the local Favre-averaged physical conditions, i.e. the

122 input vector  $\varphi$  for the delay time interpolation considers the density-average values for each of absolute

123 pressure, unburnt temperature, equivalence ratio and residuals mass fraction (Eq. 1).

124 
$$\varphi = \varphi \left( \tilde{p}, \tilde{T}_{u}, \tilde{\Phi}, \tilde{Y}_{EGR} \right)$$
(1)

125 The  $\varphi$  vector lists the independent variables that govern a multiple interpolation technique whose result is the 126 AI delay time  $\tilde{\tau}$ . In this study the Andrae et al. [19] Toluene Reference Fuel (TRF) mechanism is adopted to 127 generate a detailed look-up table of AI delays reproducing the autoignition behavior of a commercial RON95 128 European gasoline, corresponding to the fuel quality used in the experiments. Once the local  $\tilde{\tau}$  is known, it 129 are he time interpreted in the Livergood and Wu [20] or in the Laforsses et al. [21] models

can be time-integrated in the Livengood and Wu [20] or in the Lafossas et al. [21] models.

The limitation of the crude use of the cell-wise average  $\tilde{\tau}$  value to represent the local reaction rate is the 130 concept that a perfectly uniform value of pressure, unburnt temperature, equivalence ratio and residuals mass 131 fraction is assumed in the cell. As a consequence, every fluid cell is considered as a laminar well-stirred 132 reactor. Even in a RANS framework, ensemble average turbulence may affect the local thermal and mixing 133 states around the mean value which could, in turn, induce variations in the reactivity of the unburnt charge. 134 Such an effect would be completely neglected by using a unique  $\tilde{\tau}$  value. Therefore the model is extended to 135 provide information regarding not only the average knock onset but also its dispersion around the mean 136 value; details are presented in the next sections. 137

# 138 **PDF-Knock Model Equations**

Two additional transport equations are introduced to account for the statistical reconstruction of the physical
 states which may simultaneously be present in each fluid cell. Their dispersion around the mean value is

- 141 originated by the local turbulence intensity, ultimately leading to two independent knock precursors and to a
- statistically-based knock prediction. Dedicated transport equations are solved to account for local values of
- unburnt enthalpy and mixture fraction variance,  $\tilde{h}_{\mu}^{"2}$  and  $\tilde{Z}^{"2}$  respectively. They are reported in Eq. 2 and 3.

144 
$$\frac{\partial \overline{\rho} \widetilde{h^{"}_{u}}}{\partial t} + \frac{\partial}{\partial x_{j}} \left[ \overline{\rho} \widetilde{v}_{j} \widetilde{h^{"}_{u}}^{2} - \left( \overline{\rho} D_{\widetilde{h^{"}_{u}}} + \frac{\mu_{t}}{\sigma_{t}} \right) \frac{\partial \widetilde{h^{"}_{u}}}{\partial x_{j}} \right] = 2 \frac{\mu_{t}}{\sigma_{t}} \left( \frac{\partial \widetilde{h_{u}}}{\partial x_{j}} \right)^{2} - \frac{\overline{\rho}}{\tau_{Z} (Re_{t})} \widetilde{h^{"}_{u}}$$
(2)

145 
$$\frac{\partial \bar{\rho} \bar{Z}^{\tilde{n}_2}}{\partial t} + \frac{\partial}{\partial x_j} \left[ \bar{\rho} \tilde{v}_j \bar{Z}^{\tilde{n}_2} - \left( \bar{\rho} D_{\bar{Z}^{\tilde{n}_2}} + \frac{\mu_t}{\sigma_t} \right) \frac{\partial \bar{Z}^{\tilde{n}_2}}{\partial x_j} \right] = 2 \frac{\mu_t}{\sigma_t} \left( \frac{\partial \tilde{Z}}{\partial x_j} \right)^2 - \frac{\bar{\rho}}{\tau_{Z}(Re_t)} \bar{Z}^{\tilde{n}_2}$$
(3)

The difference from the standard transport equations used for Favre-average unburnt enthalpy  $\tilde{h}_u$  and mixture fraction  $\tilde{Z}$  is condensed in the dissipation terms,  $-\frac{\bar{p}}{\tau_Z(Re_t)}\tilde{h}_u^{"2}$  and  $-\frac{\bar{p}}{\tau_Z(Re_t)}\tilde{Z}^{"2}$  respectively. They are a function of the turbulent Reynolds number  $Re_t$ , from which a turbulent relaxation time-scale  $\tau_Z(Re_t)$  is expressed from local values using the approach proposed by Fox [22] and reprised by Subramanian et al. [23]. The relaxation time-scale  $\tau_Z(Re_t)$  is calculated based on the two equation k- $\varepsilon$  turbulence model and on a  $C_Z$  parameter, and it is calculated as in Eq. 4:

152 
$$\tau_Z(Re_t) = C_Z(Re_t)^{-1} \frac{k}{\varepsilon}$$
(4)

- 153 The  $C_Z$  variable links the local flow turbulence to the variance dissipation rate. To this aim, it is expressed as
- a function of the local turbulent Reynolds number  $Re_t$  as proposed in [23] and illustrated in Figure 1. A
- moderate dependence on the local  $Re_t$  is visible in Figure 1, and a first order approximation of this

156 formulation would be to consider  $C_Z = 2.2$ .

157

158 Figure 1. Variance dissipation rate  $C_Z$  parameter as a function of the local turbulent Reynolds number  $Re_t$ .

For low turbulent conditions (i.e. low  $Re_t$ ), a small value of the  $C_Z(Re_t)$  parameter is calculated, resulting in a long turbulent relaxation time-scale  $\tau_Z(Re_t)$  from Eq. 4. As a consequence, the variance destruction operated by turbulence-operated mixing in Eq. 2 and 3 is slow and a high probability to find in-cell far from average states is accounted for. The opposite is verified for highly turbulent conditions. The perturbation of

162 average states is accounted for. The opposite is verified for highly turbulent conditions. The perturbation of 163 the local fluid state is not arbitrarily imposed, but it is derived from transport equations originating from

- 164 turbulence intensity itself, hence no artificial or user-imposed variation of flow variables is introduced.
- 165 Equations 2 and 3 constitute the fundaments of the statistical treatment of the presented knock model and

166 their application will be described in the next sections.

- 167 Finally, despite the absence of explicit spray-related terms in Eq. 2 and 3, the fuel spray affects variance
- fields by promoting gradients in the mean field of both  $\tilde{Z}$  and  $\tilde{h}_u$  due to fuel evaporation and evaporative
- 169 cooling, respectively. This leads to variance production, as accounted for by the first term on the RHS of Eq.

2 and 3. Also, the spray-induced turbulence acts as a local thermo-mechanical mixer, which is considered by
 the dissipation terms on the RHS of Eq. 2 and 3.

#### 172 Statistical Description of In-Cell Reaction Rate

Both mean values and their variances are considered for enthalpy h and mixture fraction Z. As for cell-

averaged values, these are calculated from standard Favre-averaged Navier-Stokes transport equations,
whereas local variance values are derived from the presented two additional transport equations (Eq. 2 and
3).

As a first step, the mixture fraction Z is examined. Given the mean  $\tilde{Z}$  and the variance  $\tilde{Z^{"2}}$ , a normal

Gaussian distribution around the mean value in the mixture fraction space is assumed, whose spreading is represented by  $\widetilde{Z^{n_2}}$ . The probability P(Z) to find the generic Z mixture quality in the cell volume is represented by Eq. 5.

181 
$$P(Z) = \frac{1}{\sqrt{Z^{"2}}\sqrt{2\pi}} \cdot exp\left[-\frac{(Z-\tilde{Z})^2}{2\cdot \tilde{Z}^{"2}}\right]$$
(5)

182 If a single variable fluctuation was of interest, an analogous treatment could be carried out for enthalpy *h*. 183 However, in this model both mixture fraction *Z* and unburnt enthalpy  $h_u$  are affected by turbulence, as 184 expressed by the variance values  $\tilde{h}_u^2$  and  $\tilde{Z}^2$ . Their joint effect has to be accounted for in each single cell 185 and it is evaluated using a multi-variate Gaussian distribution, reported in its general form in Eq. 6 and 186 considering a correlation coefficient  $\rho_{Zh}$  whose meaning will be described later.

187 
$$P(Z,h_u) = \frac{1}{2\pi \sqrt{\tilde{z}^{\tilde{u}_2}} \sqrt{\tilde{h}^{\tilde{u}_2}} \sqrt{1-\rho_{Zh}^2}} \cdot exp\left\{-\frac{1}{2(1-\rho_{Zh}^2)} \cdot \left[\frac{(\tilde{Z}-\langle \tilde{Z} \rangle)^2}{\tilde{Z}^{\tilde{u}_2}} + \frac{(\tilde{h}-\langle \tilde{h} \rangle)^2}{\tilde{h}^{\tilde{u}_2}} - \frac{2\rho_{Zh}(\tilde{Z}-\langle \tilde{Z} \rangle)(\tilde{h}-\langle \tilde{h} \rangle)}{\sqrt{\tilde{Z}^{\tilde{u}_2}} \sqrt{\tilde{h}^{\tilde{u}_2}}}\right]\right\}$$
(6)

A simplification of Eq. 6 could be introduced by assuming mixture fraction *Z* and unburnt enthalpy  $h_u$  as uncorrelated variables, implying  $\rho_{Zh} = 0$  and leading to the simplified form in Eq. 7. This approximation is only used at this initial stage to describe the multi-variate model for the cell as a function of the local turbulence level.

192 
$$P(Z, h_u) = \frac{1}{2\pi \sqrt{Z^{\tilde{r}_2}} \sqrt{h_u^{\tilde{r}_u^{\tilde{u}}}}} \cdot exp\left\{-\frac{1}{2} \cdot \left[\frac{(\tilde{Z} - \langle \tilde{Z} \rangle)^2}{Z^{\tilde{r}_2}} + \frac{(\tilde{h} - \langle \tilde{h} \rangle)^2}{h_u^{\tilde{r}_u^{\tilde{u}}}}\right]\right\}$$
(7)

As a final step, the mixture fraction space is converted into an equivalence ratio one and the unburnt temperature  $T_u$  is substituted to enthalpy through Eq. 8 and 9.

195 
$$\widetilde{T^{"2}_{\ u}} = \frac{\widetilde{h^{"2}_{\ u}}}{c_p}$$
(8)

196 
$$\widetilde{\Phi^{"2}} = \alpha_{st} \cdot \frac{\widetilde{Z^{"2}}}{\widetilde{Y}_{O_2} + \widetilde{Y}_{N_2}}$$
(9)

In Eq. 8  $c_p$  is the isobaric mixture specific heat, while in Eq. 9  $\alpha_{st}$  is the stoichiometric air-to-fuel ratio of 197 the fuel-air mixture and  $\tilde{Y}_{O_2}$  and  $\tilde{Y}_{N_2}$  are the mass fractions of oxygen and nitrogen respectively. From a 198 mathematical point of view, this treatment stands as a presumed statistical reconstruction of all the possible 199 combinations of  $(\Phi, T_u)$  which may exist in the cell and whose dispersion around the mean value is given by 200 the local turbulent time scale. The expression reported in Eq. 7 represents the probability of a given  $(\Phi, T_u)$ 201 state to be present in the cell volume. The probability is maximum for the mean value pair ( $\tilde{\Phi}, \tilde{T}_{u}$ ), while it is 202 progressively reduced for far-from-average states, although it is not null for these; this anticipates the 203 limitation of a single AI delay to describe the whole cell reactor. The statistical two-dimensional model for 204

the fluid cell is graphically resumed in Figure 2 for different levels of turbulence, which is reflected by the amplitude of the multi-variate Gaussian model. The use of normal distribution for mixture fraction is motivated to keep the model assumptions to a minimum and to allow the use of a well-established multivariate Gaussian distribution on Z and  $h_u$ . However, beta-distribution is another candidate choice for mixture fraction statistical representation, although it relevantly complicates the definition of a bi-variate distribution function such as the one in Eq. 6

210 function such as the one in Eq. 6.

Figure 2. Multi-variate Gaussian-PDF distribution of physical states for the fluid cell in the presumed-PDF knock model. For the same most probable condition ( $\tilde{\Phi}$ ,  $\tilde{T}_u$ ), increasing turbulence intensity levels (from left to right) lead to a more effective mixing and to a probability reduction for far from average states to exist.

For the sake of numerical implementation, the multi-variate Gaussian distribution of physical conditions

 $(\Phi, T_u)$  is discretized in an arbitrary number of physical states. In the present study, a cell-wise discretization

step of half a standard deviation is adopted for both equivalence ratio and temperature, i.e. it is based on the

local values of  $\sqrt{\overline{T''_u}^2/2}$  and  $\sqrt{\overline{\Phi''^2}}/2$ . Finally, a clipping distance from the mean value must be chosen in order to bound a finite in-cell physical space: in the present analysis a clipping is adopted at two standard

deviations of each variable, i.e.  $\pm 2 \cdot \sqrt{\overline{T''_u}}$  and  $\pm 2 \cdot \sqrt{\overline{\Phi''}}$ . A consequence of this is that approx. 95% of the

overall probability of mixture states is accounted for. Each of the two independent variables is therefore
 divided into 9 discrete values and the distribution of the in-cell states counts 9<sup>2</sup> conditions. Sensitivity
 analyses showed that this is a balanced compromise between the resolution of the discretized distribution and

the amplitude of the simulated states. The result of the outlined procedure is a discrete clipped multi-variate

Gaussian distribution. Due to the discretization operation and the boundary truncation, a final re-

normalization is carried out to re-normalize the sum of all the represented discrete states to unity.

The presence of the correlation coefficient  $\rho_{Zh}$  in Eq. 6 is used here to account the degree of relationship between unburnt temperature variation and mixture fraction. This is needed since this is a likely scenario in a modern GDI unit, where intense fuel stratification is observed. Charge non-homogeneity may persist until the end of the compression stroke, and it causes temperature inhomogeneity due to the dependency of the specific heat on mixture quality. The correlation coefficient  $\rho_{Zh}$  is calculated in the model at each iteration through the analysis of the in-cylinder instantaneous  $\tilde{Z}$  and  $\tilde{h}_u$  fields and it is modelled using a Pearson-like formulation as in Eq. 10:

234 
$$\rho_{Zh} = \frac{\sigma_{Zh}}{\sigma_{\widetilde{Z}} \cdot \sigma_{\widetilde{h}}} = \frac{\sum_{i} [(\widetilde{Z}_{i} - \langle \widetilde{D}_{i} \rangle) \cdot (\widetilde{h}_{u,i} - \langle \widetilde{h}_{u} \rangle)]}{\sqrt{\sum_{i} (\widetilde{Z}_{i} - \langle \widetilde{Z} \rangle)^{2}} \cdot \sqrt{\sum_{i} (\widetilde{h}_{u,i} - \langle \widetilde{h}_{u} \rangle)^{2}}}$$
(10)

In Eq. 10, the  $\sigma_{\tilde{Z}}$  and  $\sigma_{\tilde{h}}$  terms are the standard deviations of the mean Favre-average in-cylinder  $\tilde{Z}$  and  $\tilde{h}_{u}$ fields. Therefore, the  $\rho_{ZT}$  coefficient is dynamically calculated at each iteration based on the instantaneous modeled mean  $\tilde{Z}$  and  $\tilde{h}_{u}$  fields, from which the spatial average  $\langle \tilde{Z} \rangle$  and  $\langle \tilde{h}_{u} \rangle$  values are calculated. The  $\rho_{Zh}$ term is found to be always negative: high  $\tilde{Z}$  cell-values (i.e. rich-in-fuel regions) are more likely associated to low  $\tilde{h}_{u}$ . This is a consequence of the relationship between  $\tilde{Z}$  and  $\tilde{h}_{u}$  deriving from the mixture isobaric specific heat. The instantaneous local  $\rho_{Zh}$  correlation coefficient modifies the bi-variate Gaussian model for

- the in-cell conditions as illustrated in Figure 2 for several  $\rho_{Zh}$  parameter values. In Figure 3 the equivalence
- ratio is used instead of  $\tilde{Z}$  to represent fuel concentration. Hotter states are associated with leaner mixtures
- (bottom-right side in Figure 3) and the same is for cooler and richer conditions (upper-left side in Figure 3),

while hot and rich (upper-right) or cool and lean (lower-left) combinations are less probable.

Figure 3. Bi-variate Gaussian distribution for the in-cell statistical states as a function of the  $\rho_{ZT}$  correlation coefficient:  $\rho_{Zh} = 0$ (left, uncorrelated equivalence ratio and  $\tilde{h}_u$ ),  $\rho_{Zh} = -0.5$  and  $\rho_{Zh} = -0.75$  (middle and right, negatively correlated equivalence ratio and  $\tilde{h}_u$ ).

249

245

#### 250 Knock Precursor Variance

From a general point of view, once a global reaction rate  $\tilde{\omega} = \tilde{\tau}^{-1}$  is known a knock precursor growth rate can be calculated in the same way as the Livengood and Wu knock integral function  $\tilde{I}$ . This can be transported as a generic scalar with an equation as Eq. 11.

254 
$$\frac{\partial \bar{\rho}\tilde{I}}{\partial t} + \frac{\partial}{\partial x_j} \left[ \bar{\rho}\tilde{v}_j \tilde{I} - \left( \bar{\rho}D_{\tilde{I}} + \frac{\mu_t}{\sigma_t} \right) \frac{\partial \tilde{I}}{\partial x_j} \right] = \bar{\rho}\widetilde{\omega}$$
(11)

The difference introduced by the presumed-PDF treatment lies in the definition of the  $\tilde{\omega}$  term. Since a variety of physical states is statistically possible in the single fluid cell, a distribution of reaction rates is also to be considered in the cell volume. The theoretical global reaction rate follows a more complex definition and it is expressed as in Eq. 12.

259 
$$\widetilde{\omega} = \int_{V} P(\Phi, T) \cdot \omega(\Phi, T) dV = \int_{V} P(\Phi, T) \cdot \frac{1}{\tau(\Phi, T)} dV$$
(12)

The calculation of the integral can be numerically challenging since an analytical function of  $\tilde{\omega}(\Phi, T)$  is not known a priori, hence an assumption is made considering the dispersion of the in-cell reaction rates as the sum of a mean term and a contribution due to fluctuations. This last can be either positive or negative, i.e. it can accelerate or slow down the global reaction rate depending on the considered local physical state. Since the focus of this study is on the earliest probability that a portion of a fluid cell experiences autoignition, just the faster than average part of the reaction rate distribution is of interest.

These arguments lead to the representation of the knock inceptor reaction rate  $\omega_{PDF,peak}$  by means of an average value  $\omega_{PDF,aver}$  and an accelerating contribution given by its root mean square (rms)  $\omega_{rms}$  value (Eq. 13).

269 
$$\omega_{PDF,peak} = \omega_{PDF,aver} + \omega_{rms}$$

7

(13)

270 The first term on the right side is obtained by a PDF-weighted averaging operation of the population of

reaction rates calculated based on the discrete multi-variate PDF space, hence the  $\omega_{PDF,aver}$  name (Eq. 14).

272 
$$\omega_{PDF,aver} = \sum_{i=1}^{\Phi_{tot}} \sum_{j=1}^{T_{tot}} P(\Phi_i, T_j) \cdot \frac{1}{\tau(\Phi_i, T_j)} d\Phi dT$$
(14)

273 The second term is calculated as the difference between the  $\omega_{PDF,aver}$  term and the faster than average

reacting state considered in the discrete cell representation. It represents the root mean square of the faster

than average reaction rates within the fluid cell. Following an analogous  $\pm 2 \cdot \sqrt{\tau^{"2}}$  clipping for AI delays, this reads as Eq. 15 and corresponds to the reaction rate of the 2.5% of the fastest-reacting portion.

277 
$$\omega_{+2\sigma} = \frac{1}{\tau}\Big|_{-2\sigma}$$
(15)

Finally, the  $\omega_{rms}$  term is calculated as in Eq. 16 and it represents the net increase in reaction rate due to the accelerating contribution of the statistically present faster than average states.

280 
$$\omega_{rms} = \frac{\tau|_{PDF,aver} - \tau|_{-2\sigma}}{\tau|_{PDF,aver} \cdot \tau|_{-2\sigma}}$$
(16)

Once all the needed terms are available, the time integration of a knock integral function can be calculated considering Eq. 13, and it is manipulated as in Eq. 17 to split the integration of the mean reaction rate and its statistically faster reacting portion:

284 
$$\tilde{I} = \int_{t_0}^t \tilde{\omega} \, dt = \int_{t_0}^t \omega_{PDF,aver} \, dt + \int_{t_0}^t \omega_{rms} \, dt \tag{17}$$

The decomposition in Eq. 17 immediately leads to the independent calculation of two knock precursors,  $\tilde{I}_{PDF,aver}$  and  $\tilde{I}_{rms}$  respectively (Eq. 18). The former expresses the average chemical reaction rate towards autoignition, while the latter is the precursor variance contribution given by the turbulence intensity.

288 
$$\tilde{I}_{PDF,peak} = \tilde{I}_{PDF,aver} + \tilde{I}_{rms}$$
 (18)

The average knock precursor and its variance are modelled through dedicated transport equations, Eq. 19 and 20 respectively.

291 
$$\frac{\partial \bar{\rho} \tilde{I}_{PDF,aver}}{\partial t} + \frac{\partial}{\partial x_j} \left[ \bar{\rho} \tilde{v}_j \tilde{I}_{PDF,aver} - \left( \bar{\rho} D_{\tilde{I}_{PDF,aver}} + \frac{\mu_t}{\sigma_t} \right) \frac{\partial \tilde{I}_{PDF,aver}}{\partial x_j} \right] = \bar{\rho} \omega_{PDF,aver}$$
(19)

292 
$$\frac{\partial \bar{\rho} \tilde{I}_{rms}}{\partial t} + \frac{\partial}{\partial x_j} \left[ \bar{\rho} \tilde{v}_j \tilde{I}_{rms} - \left( \bar{\rho} D_{\tilde{I}_{rms}} + \frac{\mu_t}{\sigma_t} \right) \frac{\partial \tilde{I}_{rms}}{\partial x_j} \right] = \bar{\rho} \omega_{rms}$$
(20)

Since the model aim is to track an autoignition probability for the fluid cell, the heat release due to potential knock is purposely not simulated. If autoignition heat was simulated, when AI is met for a portion of the cell due to faster than average states it would affect all the other realizations (e.g. the average knock onset) by varying the local thermo-physical conditions, while it is more interesting to transport both average and maximum probability states within the Gaussian-based model and independently track their time-history.

298

# 299 Experimental Apparatus and Engine Knock Characterization

Measurements were performed on a single-cylinder optically accessible DISI engine; whose main
 specifications are carefully detailed in [24] and here briefly resumed for the sake of completeness in Table 1

302 along with the operating conditions. The crank angle reference is made to the TDC at the end of

303 compression.

Displacement	$\approx 399 \text{ cm}^3$
Bore	79.0 mm
Stroke	81.3 mm
Connecting Rod	143 mm
Compression Ratio	10:1
Injection pressure	100 bar
Engine Speed	$\approx 2000 \text{ rpm}$
Boost pressure	0.5 bar
Spark Advance	15 CA bTDC

304 Table 1. Single cylinder optically accessible SI engine characteristics.

The engine is equipped with the cylinder head of a 1.4 litre currently made SI turbocharged power unit. The 305 wall-guided fuel injection system features a side-mounted injector with a six-hole configuration and the 306 spark plug is centrally located, as reported in Figure 4. Optical access is ensured through an 18 mm-thick 307 fused silica window fixed on the piston crown featuring a Bowditch design [25] with a 45 degree UV-308 enhanced mirror. Self-lubricating piston rings ensured oil-free operation, thus avoiding contamination of the 309 visible field of view. More details into the application of optical techniques on this engine and other specific 310 challenges are available in [26, 27]. Coolant and lubricant temperature were monitored and maintained at 311 330 K using a thermal conditioning unit. Engine speed was set at 2000 rpm, while start of injection was 312 triggered at 300 CA bTDC with a single-pulse strategy at a pressure equal to 100 bar. The overall air-to-fuel 313 ratio was set close to stoichiometry ( $\lambda \approx 1.05$ ) and monitored using an oxygen sensor on the exhaust line, with 314 an accuracy of  $\pm 1\%$ . 315

316

317

318 Figure 4. Experimental apparatus for the optically accessible SI engine.

A turbocharged operating condition was examined in this study, with 0.5 bar boost pressure and intake 319 manifold temperature around 315 K. Spark timing was set at 15 CA bTDC, and this also constituted the 320 trigger for recording the optical measurements. The adoption of an instrumented GDI turbocharged unit 321 represents an optimal testing for the presented knock model, allowing to include in the analysis the effects of 322 323 stratified mixture distribution and high end-gas thermal loading common to most of the modern SI production units. A dataset of in-cylinder pressure measured (with a resolution of 0.2 CA) during 173 324 consecutive firing cycles were recorded through a piezo-electric transducer (that featured an accuracy of 325  $\pm 1\%$ ) flush-mounted on one side of the combustion chamber between an intake and an exhaust valve. The 326 experiments were carried out using a commercial RON95 gasoline, and a knock-affected condition is 327

328 observed from the cycle-resolved in-cylinder pressure derivative reported in Figure 5 (left). An arbitrary

limit of pressure derivative was chosen equal to 5 bar/CA to discern between knocking and non-knocking

cycles. The result of this filtering is that 109 out of 173 cycles exceed this criterion, depicting a 63% fraction

of experimentally knocking cycles for this operation. The CA of knock onset for this subset of cycles is reported in Figure 5 (right), and the mean CA for knock onset for this portion of cycles is +11.9 CA aTDC,

with a standard deviation equal to 3.2 CA. This illustrates the 'run-away' behavior of knock, with the

334 specific pressure oscillations being more evident for cycles at the end of the recorded dataset.

335336

Figure 5. Cycle-resolved in-cylinder pressure derivative (left) and CA of knock onset for the subset of knocking cycles (right).

337 Cycle resolved visualization was performed for 100 consecutive cycles out of the 173 via a CMOS camera (Optronis CamRecord 5000 – 512 x 512 pixel, 8-bit pixel digitization and 5000 frame per second at full chip) 338 equipped with a 50 mm focal Nikon lens. The exposure time was fixed at 166.7 µs and the dwell time 339 between two consecutives images was 200 µs (2.4 CAD at 2000 rev/min). A custom designed image 340 341 processing using Vision Assistant of National Instruments allowed to retrieve quantitative information from the combustion visualizations even for images with low signal to noise ratio. As sketched in Fig. 6 (a-e), 342 after the application of an appropriate circular mask (a->b) to cut the spurious light from reflections at the 343 boundaries of the optical window of the piston crown, a look-up table (LUT) transformation [28] was used to 344 adjust the brightness at 174, contrast at 73 and the gamma value at 0.76 (b->c). Then, thresholding was 345 performed by fixing the minimum image intensity at 21 on 256 grey-scales (Fig. c->d). Thus, images were 346 segmented into two regions, foreground and background respectively, obtaining a binarized image [29]. 347 Finally, the contours of flames were defined (d->e) and the related coordinates in pixels were stored. In order 348 349 to perform a frequency map of autoignition events, only the border coordinates of the flames in the end-gas detected at fixed delay from the spark timing were considered. It should be noted that the difference between 350 the optical window and the engine bore determined a 5.25 mm thick blind circular crown; therefore, only 351 autoignition flames sufficiently large to cover the distance between the wall and the optical crown limit can 352 be considered for the evaluation of autoignition maps. 353

354

355 Figure 6. Sketch of the image processing steps.

The experimentally measured knock probability is reported in Figure 7 through a spatial map of the

normalized autoignition occurrence. The probability for the end-gases to undergo autoignition is assessed by

358 means of the optical analysis carried out through the transparent piston window which allowed to identify the

- distribution of the end-gas regions subjected to knock; the peak probability was found on the exhaust side
- 360 (top part in the picture), although knock is also probable on the intake side (low side in the picture).

362 Figure 7. Map of normalized autoignition location (left) and CA of knock onset for the subset of knocking cycles (right).

# 363 **3D CFD simulations**

The 3D CFD analyses presented in this paper are carried out by means of a customized version of STAR-CD 364 v4.22. Time varying pressure boundary conditions derive from the experiments and they are used to validate 365 a 1D model of the engine, from which the corresponding temperature trace is extracted. Turbulence is 366 modelled though the k-E RNG turbulence model for compressible flows. The grid adopted for the simulations 367 is reported in Figure 8 and it reproduces the whole combustion chamber and both the intake and exhaust 368 ports. A close-up of the spark plug geometry and of the injector region are presented in Figure 8 as well. The 369 total number of cells is approx. 1.48 M and 430000 at BDC and TDC respectively, while the average cell-370 size is about 0.55 mm throughout the simulation. 371

372

361

Combustion is modelled with the Flame Surface Density (FSD) ECFM-3Z model [30], coupled with a 374 relatively simple algebraic ignition model based on a flame profile deposition to account for flame kernel 375 formation [31]. The fuel injector is a 6-hole full-cone GDI one whose nominal data are reported in Table 2 376 and whose nozzle orientation is sketched in Figure 9. The multi-hole liquid spray is modelled using a 377 Lagrangian approach, where the fuel atomization is replaced by a Rosin-Rammler droplet distribution 378 function. Nozzle-specific mass flow rate is prescribed as to reproduce experimental flow unbalance between 379 the nozzles. The effective nozzle diameter is evaluated using the Kuensberg 1D model [32]. The secondary 380 break-up is modelled by the Reitz and Diwakar approach [33]. Finally, spray is validated against experiments 381 carried out in a spray bomb at an injection pressure of 100 bar; the spray morphology and the penetration 382 curve are reported in Figure 10 at two instants after Start Of Injection (SOI), 400 ms and 800 ms 383 respectively. In Figure 10 the penetration curve of the simulated spray is also reported and it confirms the 384 satisfactory agreement with the experiments. 385

Figure 8. Computational grid (top) and spark plug and injector region detail (bottom).

- Finally, knock is modelled by means of the presented presumed-PDF knock model, which is coupled with
- 387 the STAR-CD solver through in-house developed user-coding.

Nominal nozzle diameter	0.14 mm
Nominal nozzle length	0.196 mm
Number of nozzles	6

394

# 395 **Results**

396 The set of pressure traces from each individual cycle, measured with 1% accuracy and 0.2 CA resolution, is

reported in Figure 11, alongside with the calculated ensemble average trace and the extreme measured

- 398 cycles. The combustion pressure trace from simulation is also reported in Figure 11 and the agreement
- between the CFD result and the ensemble average pressure trace assesses the validity of the simulation to represent the mean flame development behaviour. This is further confirmed by the agreement of the
- 401 combustion indicators for 10%, 50% and 90% of fuel burnt.

402 403

404 Figure 11. Left: CFD pressure trace (black solid line) compared with the experimental extreme cycles (red dashed lines) and 405 ensemble average pressure traces (red solid line). Right: comparison of the main combustion phasing indicators for CFD and 406 ensemble average of experimental cycles.

407 The mean propagating flame front is depicted in Figure 12 by the isosurface of the Favre-averaged

combustion progress variable  $\tilde{c}$  at  $\tilde{c} = 0.5$  value. Flame initiation is compared to the experimental imaging to analyze the simulation accuracy in representing the flame kernel evolution. Figure 13 shows that a flame kernel development towards the exhaust side of the combustion chamber (top side) is recurrently observed for three selected cycles at +9 CA aSOC, representative of a slow, an average and a fast burning cycles (cycle no. 31, no.75 and no.109, respectively). Despite the relatively simple flame deposition model for spark ignition, numerical simulation confirms this tendency by means of combustion progress variable  $\tilde{c}$  field and explains this behavior as due to mean flow convection of the reaction zone given by the residual tumble

415 motion.

416

- 422

#### 423 Knock Prediction Simulation

424 The presented knock model is applied to the simulated mean realization of combustion. In Figure 14 the

425 unburnt temperature and the equivalence ratio field are represented at +10 CA aTDC. A detailed analysis of

the end-gas condition is carried out for this CA. End-gases are identified through a conditioning on the Favre-average reaction progress variable  $\tilde{c}$ , by filtering cells whose  $\tilde{c}$  value is below 0.8. Figure 15 shows a

428 scatter plot of the mixture composition against unburnt temperature, highlighting the promoted heating of the

429 lean portion of peripheral mixture visible in Figure 14.

430

432

431 Figure 14. Unburnt temperature (left side) and equivalence ratio field (right side) at +10 CA aTDC.

434 The field of average AI delay times and of its root mean square are reported in Figure 16. While the former

435 field (left side), related to the gas phase average reaction rate (expressed as the inverse of the local AI delay

time), shows local minima at the periphery of the intake valve and around the injector cavity, the latter (right side) visually suggests that local turbulence induces a more relevant degree of reactivity fluctuation on the

438 exhaust side of the combustion chamber.

440 Figure 16. Average AI delay time field (left side) and delay root mean square field (right side) at +10 CA aTDC.

441 The peak reaction rate and its average counterpart are illustrated in the scatter plots in Figure 17 for the end-

442 gas region at TDC, +10 CA aTDC and +20 CA aTDC. It is interesting to observe that the promotion of

443 autoignition tendency given by the faster than average reacting states is present at all combustion stages, as

stated by the population of fluid cells cleary lying above the 45-degree line. This is verified for relatively low reaction rates (e.g. at TDC) as well as for highly reacting conditions (e.g. +10 CA aTDC).

447 Figure 17. Scatter plots of average reaction rate  $\omega_{PDF,aver}$  (Eq. 14) against peak reaction rate  $\omega_{PDF,peak}$  (Eq. 13). for the end-gas 448 region: TDC (left), +10 CA aTDC (middle), +20 CA aTDC (right).

The field of the average knock precursor  $\tilde{I}_{PDF,aver}$  and of its root mean square  $\tilde{I}_{rms}$ , as calculated by Eq. 19

and 20, are represented in Figure 18. The average knock precursor field shows an evenly distributed

451 population at both the exhaust and the intake sides, although the exhaust side of the combustion chamber

452 (left side in figures) appears slightly more prone to knock. This is confirmed by the experiments, where

453 knock onset locations were measured on both sides of the optical access. Furthermore, a  $\tilde{I}_{PDF,aver}$  value

below unity allows to consider the whole chamber as knock safe from an average point of view at such crank

angle. Nonetheless, the magnitude of the precursor  $\tilde{I}_{rms}$  field is relevant compared to the mean value. In

456 particular, its additional contribution on the exhaust side points out that turbulence-induced perturbations of 457 the reaction rate lead to more probable knock in that region of the combustion chamber, despite the average

458 realization is not knocking at +10 CA aTDC.

459

468

446

Figure 18. Average knock precursor  $\tilde{\mathbf{I}}_{PDF-aver}$  field (left side) and precursor root mean square field  $\tilde{\mathbf{I}}_{rms}$  (right side) at +10 CA aTDC.

The degree of statistical knock tendency of the end-gases is further analyzed through the ratio of peak over average reaction rates as a function of the Favre-averaged fields of unburnt temperature and of the equivalence ratio, illustrated in Figure 19. Such analysis clearly shows that the leanest and hottest portion of the end gases, located on the exhaust side of the cylinder, are also those more subject to turbulence-induced

reaction rate increase. This is accounted for by the  $\rho_{Zh}$  correlation coefficient calculated as in Eq. 10. This confirms the experimental evidence indicating the exhaust-side region as a knock critical area.

- 469 Figure 19. Scatter plot of the ratio of peak over average reaction rate for the unburnt mixture at +10 CA aTDC as a function of the 470 unburnt temperature (left) and of the equivalence ratio (right).
- Finally, the volume of the end-gas region where the autoignition criterion is met for both the average knock
- precursor  $\tilde{I}_{PDF,aver}$  and the peak precursor  $\tilde{I}_{PDF,peak}$  is illustrated in Figure 10 together with the simulated mass fraction burnt (MFB) curve.

Figure 20. Autoignition volume as predicted by the average  $\tilde{I}_{PDF,aver}$  and the peak  $\tilde{I}_{PDF,peak}$  knock precursors (black lines), together with the ensemble average MFB curve (red line).

477

474

# 478 **Definition of Knock Probability in RANS**

The knock prediction given by the presented model is analysed to reconstruct a fraction of knocking cycles to be compared with the experimental evidence. Knock occurrence is observed through the mass fraction of fuel which is burnt at knock onset (hereafter  $MFB_{KO}$ ). If the cell-average  $\tilde{\tau}$  value alone was used, the only information available from the analysed engine would be that the ensemble average cycle is knocking after +15CA aTDC, but no conclusions could be inferred regarding the dispersion around this value.

The additional information given by the presented presumed-PDF model is the estimation of a probability 484 function around the mean value, which is obtained from the knock occurrence of the peak knock precursor 485  $\tilde{I}_{PDF,peak}$ . This is used to define a second knock phasing indicator, i.e.  $MFB_{KO,peak}$ . Given the stochastic 486 occurrence of knock, it is reasonable to assume a normal Gaussian distribution for knock occurrence, which 487 is centred in  $MFB_{KO,mean}$  with a standard deviation  $\sigma_{MFB_{KO}}$  derived from  $MFB_{KO,peak}$ . In the considered 488 case,  $MFB_{KO,mean}$  is equal to 83.8% while  $\sigma_{MFB_{KO}}$  is 39.8%. These values are based on a minimum non-null 489 value of autoigniting volumes in the end-gas imposed as 1 mm<sup>3</sup> needed to avoid the spurious autoignition of 490 individual cells to be considered. Based on these indicators a probability function of  $MFB_{KO}$  is reconstructed 491 following Eq. 21 and it is illustrated in Figure 21. 492

493 
$$P(MFB_{KO}) = \frac{1}{\sigma_{MFB_{KO}}\sqrt{2\pi}} \cdot exp\left[-\frac{(MFB_{KO}-MFB_{KO,mean})^2}{2\cdot\sigma_{MFB_{KO}}^2}\right]$$
(21)

494

495 Figure 21. Assumed Gaussian-PDF of the percentage of burnt fuel at knock onset  $MFB_{K0}$ .

496 Given the above reconstruction for knock occurrence distribution, it is possible to calculate the cumulative

497 probability of cycles exhibiting knock before the completion of regular combustion, i.e. 100% of burnt fuel.

This is calculated as the Cumulative Distribution Function (CDF) of the above distribution, which is reported

499 calculated in Eq. 22 and illustrated in Figure 22.

500 
$$CDF(MFB_{KO}) = \frac{1}{2} \cdot \left[ 1 + erf\left(\frac{MFB_{KO} - MFB_{KO,mean}}{\sqrt{2} \cdot \sigma_{MFB_{KO}}}\right) \right]$$
 (22)

501

502

Figure 22. Cumulative Distribution Function of the percentage of burnt fuel at knock onset  $MFB_{KO}$ .

Since the region of interest is limited to the probability to have a knocking cycle before the regular 504 combustion finalization, the cumulative probability to verify this condition is given by Eq. 22 calculated at 505 the limit value, i.e.  $CDF(MFB_{KO})|_{MFB_{KO}=100\%}$ . In this case the knock frequency value is 65.8%, stating that 506 approximately 66% of the possible realizations reach the conditions for autoignition in a portion of their 507 volume, while the remaining 34% is knock-safe. This result is in very good agreement with the experimental 508 evidence showing that a fraction of 63% of the measured cycles is knocking. This information is inferred 509 from a single RANS simulation, while the average knock prediction alone would be unable to estimate any 510 knock dispersion around the mean value. 511

512 It is important to underline that the aim of the presented model is neither to substitute a multiple cycle LES

513 simulation, which remains the only way to properly simulate most of the CCV-promoting processes, nor to 514 identify the exact fraction of knocking cycles measured during the experiments. The presented presumed-

515 PDF model is a numerical tool to identify the regions of the combustion chamber which are statistically more

516 prone to autoignition, and this information is inferred by a combination of an average knock precursor and a

- 517 statistical description of the reaction rate deviation produced by local gradients and dissipated by local
- turbulent intensity. Since RANS simulations are the most appropriate tool to investigate the mean behaviour

of a fluid system (e.g. a new engine concept), the indications from the presumed-PDF model may provide

<sup>520</sup> useful statistical information on the probability to trigger potentially damaging knocking events.

# 521 Conclusions

In this paper a statistics-based knock model is presented in the context of RANS combustion simulation, 522 which couples RANS traditional equations with the transport of variances for the physical conditions 523 affecting local reaction rate. The model is based on separate transport equations for both the mixing and the 524 thermal variance originated by local mean gradients and turbulent scales. They are combined to reconstruct a 525 statistical model for the in-cell reaction rate, which is represented though a clipped multi-variate Gaussian 526 527 distribution of probability. Two independent knock precursors are transported, in order to account for both the ensemble average knock proximity and its variance around the mean value. The combined use of the 528 precursors is able to outline a statistically-based description of the in-cell reaction rate distribution. 529

530 When applied to a laboratory GDI engine with optical access, the results from the presumed-PDF knock 531 model assesses knock onset on the exhaust side of the combustion chamber. This is the area where flame 532 visualization indicated the highest knock probability, and numerical simulations showed that this region 533 suffers of lean and hot end-gases, promoting knock onset. Moreover, turbulence-induced dispersion 534 promoted reaction rate increase of the unburnt mixture in this region, making it also the highest probability 535 knock location. An overall fraction of 66% of knocking cycles is calculated, which is in close agreement 536 with the experimental 63%.

The use of a PDF-based model allows to give a quantitative estimation of the knock probability events 537 associated with an average knock occurrence condition. The statistical model is based on transport equations 538 for the variance of physical conditions (enthalpy and mixture fraction) and tracks their variability in terms of 539 knock onset variance. The presented PDF-based knock model combines both the accuracy of a detailed 540 chemical mechanism used to calculate the autoignition delay times and the applicability of a RANS-based 541 model. The presented model aims at filling the existing gap between the scarcely representative average 542 knock prediction given by traditional RANS models and the cycle-resolved knock simulation possible with 543 CPU-intensive multi-cycle LES simulations. The combination of RANS models with variance transport 544 equations allows to quantify the probability of knocking events given by turbulence-originated fluctuation of 545 end-gas pockets, and it allows RANS simulations to be directly correlated with engine test-bench acquisition. 546

# 618 Abbreviations

AIAutoignitionaSOCAfter Start of CombustionaTDCAfter Top Dead CentreBDCBottom Dead CentrebTDCBefore Top Dead CentreCACrank Angle

CCV	Cycle-to-Cycle Variability
CDF	Cumulative Distribution Function
DI	Direct Injection
DKI	Dimensionless Knock Indicator
FSD	Flame Surface Density
GDI	Gasoline Direct Injection
IMPO	Integral Modulus of Pressure Oscillations
KLSA	Knock Limited Spark Advance
КО	Knock Onset
LES	Large-Eddy Simulation
MAPO	Maximum Amplitude of Pressure Oscillations
MFB	Mass Fraction Burnt
PDF	Probability Density Function
RANS	Reynolds-Averaged Navier- Stokes
RMS	Root Mean Square
SA	Spark Advance
SI	Spark Ignition
SOI	Start of Injection
TDC	Top Dead Centre
TRF	Toluene Reference Fuel
