Abstract

We explored the relationships among Sardinian populations by means of a spatial analysis of surnames in five villages in the historical-geographical zone of Barbagia di Belvì, a mountainous area traditionally devoted to sheep-rearing and the point of departure of transhumance toward lowland areas. We collected the surnames of 19th century Sardinian populations through the *Status Animarum* (parish censuses). The structures of past populations were compared with current ones based on surnames reported in telephone directories. The lowland villages studied have been the final destination of transhumance and have a different historical, cultural and economic background. The spread of surnames in Sardinia may have occurred also by means of transhumance, occurring every year along precise routes from the pastoral mountain zones to the agricultural plains.

We used the standardized index of Chen and Cavalli-Sforza to calculate the relationships among the five villages of Barbagia di Belvì (Aritzo, Belvì, Desulo, Gadoni and Tonara). Application of non-metric Multidimensional Scaling to the isonymy matrices showed that the villages of Barbagia di Belvì form a group that has changed very little over time. Transhumance routes were studied by Spatial Autocorrelation (Moran's *I*) applied to surnames. The results suggest that there has been an appreciable admixture between the Sardinian populations of the mountain villages of the central areas and the populations of southern lowland villages.

Introduction

Surnames have a cultural origin and reflect the ethno-historical, socioeconomic and linguistic background of a given population, especially relevant in the context of population mobility (Colantonio et al., 2003; Cheshire, 2014). In “Western” countries, surnames are transmitted from father to children and are similar to a genetic marker, comparable to neutral and highly polymorphic alleles of a Y-chromosome locus (Lasker, 1985; Crow, 1983; King and Jobling, 2009a, b; King et al., 2006; Lucchetti et al., 1987; Colantonio et al., 2003; Sykes and Irven, 2000; Jobling, 2001; Jobling and Tyler-Smith, 2003; Graf et al., 2010; Boattini et al., 2012; Darlu et al., 2012; Martínez-Gonzalez et al., 2012; Winney et al., 2012). It is usual to select autochthonous DNA donors based on the original surnames of the place of residence (Manni et al., 2005; Winney et al., 2012). Using this specific surname-based approach, several genetic studies observed historical population genetic structure or past admixture events that were otherwise invisible (Hill et al., 2000; McEvoy and Bradley, 2006; Bowden et al., 2008; Larmuseau et al., 2012).

The generalized origin of surnames in Italy was decreed by ecclesiastical regulations (*Rituale Romanum*) of the Council of Trent (1545-1563). These rules also prescribed a census of the Catholic population in special registers (*Status Animarum*) indicating the individuals by their first

name and surname.

In many populations, civil sources can also be used: lists of surnames for the entire population (family heads, telephone subscribers, users of other utilities, etc.) are readily available. The relatively easy sampling, similarity with genetically inherited traits and high polymorphism make surnames particularly suitable for the study of microevolutionary processes in populations from the 17th century onward (Lucchetti et al., 2008).

In this paper we analyze the spread of the typical surnames from the central area of Sardinia.

Studies on the distribution of surnames in Sardinia have demonstrated that: they act like neutral alleles (Zei et al., 1983a, b, 1986); the migration matrices determined from the temporal differences in surname distributions agree with what is known about the history of the population and its mobility (Wijsman et al., 1984); the temporal variation of the frequency of surnames is 10 times lower than the spatial variation (Zei et al., 1986); the similarities among village populations based on the relative distribution of erythrocyte markers agree with the similarities among villages based on surname distributions (Lucchetti et al., 1987); the isonymic relationships among various Sardinian villages follow the isolation by distance model and the isonymy among nearby villages increases in time (Sanna et al., 2001, 2006). Moreover the genetic homogeneity of Sardinians, shown by the distribution of some Y-chromosome genetic markers, is not confirmed when the samples are formed on the basis of the zone of origin of the surnames of sampled individuals rather than their zone of residence (Zei et al., 2003).

It is also noteworthy that the isonymic difference/similarity among various municipalities of Sardinia is conditioned by their geographical location and historical background (Sanna et al., 2006; Orrù et al., 2008), while the Sardinian municipalities form a particular and well defined cluster when compared with other Mediterranean communities (Lucchetti et al., 2008).

The island has presented two different but complementary socioeconomic and cultural realities through the centuries. One, typical of mountainous areas, is characterized mainly by pastoral activities, while the other, typical of lowland areas, is characterized mainly by agricultural activities (Sanna and Danubio, 2008). This productive system remained the same until the second half of the 20th century (Sanna, 2006).

There were substantially two types of transhumance in Sardinia: short-range, involving movements within the same municipal territory or toward nearby villages; long-distance, from the western slopes of the Gennargentu Massif in central Sardinia to the south-western plains (Le Lannou, 1941; Ortu, 1988; Sanna and Danubio, 2008).

The Sardinian shepherds who practiced long-distance transhumance remained for about six months in the plains, where the flocks wintered: transhumance started in December and ended at the end of

April (Meloni, 1982; Sanna and Danubio, 2008). The transhumance covering the longest distances started in the villages forming Barbagia di Belvì and Barbagia di Ollolai, with migrations to the wintering areas of up to 150 km. To reach the wintering areas, the flocks of Barbagia had to cover many kilometers of highlands and plains densely populated by farmers; sometimes, en route, this created conflicts with the owners of the lands bordering the winter pastures (Le Lannou, 1941).

The spread of surnames in Sardinia may also have occurred by means of long-distance transhumance, occurring every year along precise routes from the pastoral mountain zones to the agricultural plains.

Historically, the territory of the island is divided into 34 zones (Fig. 1). This categorization (Ghiani Moi, 1964) provides important information about the territorial distribution of people in Sardinia: people living in the same zone have likely shared the same habits, living conditions, food, meteorological features, etc. We considered a subset of these zones, i.e. only the ones involved in transhumance. The point of departure of transhumance toward lowland areas was the zone of Barbagia di Belvì, a mountainous area traditionally devoted to sheep-rearing. From the genetic point of view, the population of this zone is considered the most conservative of the island (Cappello et al., 1996; Calò et al., 1998; Vona and Calò, 2006).

We obtained the frequencies of surnames of these mountain populations in the 19th century and in recent times and compared them with the current distribution of surnames in the lowland villages. These lowland populations live in a cultural and economic environment very different from that of the populations of Barbagia di Belvì.

The aims of this paper are: 1) to highlight the relationships among the Sardinian populations in relation to transhumance, and 2) to determine if transhumance resulted in appreciable admixture between the pastoral populations of the mountains and the agricultural populations of the plains.

Methods

The populations considered were those of the villages of Aritzo, Belvì, Desulo, Gadoni and Tonara, which form the historical-geographical zone of Barbagia di Belvì (Ghiani Moi, 1964), and the populations of the lowland areas, which were the traditional destination of transhumance.

In order to describe the structure of surnames in the ancient population of Barbagia di Belvì, we used the books of the *Status Animarum*, the ecclesiastic books of censuses in which the priest recorded the name and surname of the head of the household and the other family members.

The registers of all the villages of Barbagia are available only since 1840; before that, there are no years for which the parish books of all five villages are present contemporaneously. Nevertheless, we extended the analysis by considering the *Status Animarum* books of 1815 for Aritzo, Belvì and Gadoni, of 1816 for Desulo, and of 1811 for Tonara; in addition, we consulted the *Status Animarum* of 1844 for Desulo. We compared these data with the recent distribution of surnames in the transit and destination villages of transhumance obtained from telephone subscribers in 1993. The telephone directory lists the people who reflect the family groups living in a given area, so much so that this device has been frequently used in various demo-ecological and genetic analyses of Italian populations (Boattini et al., 2012; Risso et al., 2015).

Figure 2 shows the geographical distribution of the villages of Barbagia di Belvì and their long-distance transhumance routes.

Figure 2

Table 1 reports the number of records of the *Status Animarum* registered in the years considered; from each act, we extracted the surname of the householders to identify the original surnames in Barbagia di Belvì. This table also reports the number of surnames present in the telephone directories of 1993.

Table 1 - Villages of Barbagia di Belvì. Years examined, number of householders, number of individuals present in the telephone directories. In brackets, the percentage of different surnames with respect to the total number of individuals considered

	<i>Status Animarum</i>					Telephone directories
	YEARS					YEAR
	1811	1815	1816	1840	1844	1993
<i>Villages</i>						
Aritzo	-	580 (18.45)	-	479 (19.83)	-	483 (25.26)
Belvi	-	225 (30.66)	-	205 (29.76)	-	215(40.00)
Desulo	-	-	473 (18.60)	463 (17.49)	455 (17.58)	755 (25.16)
Gadoni	-	83 (51.81)	-	206 (27.18)	-	314 (29.94)
Tonara	651 (15.36)	-	-	655 (16.18)	-	729 (24.55)

The isonymic relationship between populations was calculated with the index of “standardized isonymy” proposed by Chen and Cavalli-Sforza (1983):

where R_{ij} is the coefficient of similarity between two populations i and j , x_i and x_j are the frequencies in them of the x -th surname, and the total is extended to all the surnames. The value of R_{ij} is zero when the two populations do not have any surname in common; it is 1 when the two populations share the same surnames with equal frequencies, independently of their numbers.

The isonymy index was used to produce a similarity matrix between the populations of the five villages of Barbagia di Belvì, the starting area of transhumance. Non-metric Multidimensional Scaling (nmMDS) was used to produce a synthetic plot of the isonymic relationships among the five Sardinian villages and their variation in time. The results showed that the five villages have a peculiar surname structure, very diversified and self-preserved over time. This allowed us to proceed with a subsequent spatial investigation.

When sampling locations are known, the association between genetic and geographical distances can be tested by spatial autocorrelation or geographically weighted regression methods.

Spatial autocorrelation analysis was applied to the quantitative data summarizing the genetic similarity between populations in relation to their proximity in space. In this specific case, spatial autocorrelation allows us to determine the similarity of values of the frequency of a surname between pairs of localities within arbitrary distance classes. This method allowed estimation of the spatial distribution of the selected surnames in the starting, transitional and arrival areas of transhumance in order to emphasize the specific diffusion processes of the individuals independently of the migration rates of the various localities. Spatial autocorrelation was developed by Moran (1950) and refined by Ripley (1981) and by Cliff and Ord (1981). It was first applied to biological problems by Sokal and Oden (1978a, b). The computation of spatial autocorrelation requires a set of localities represented as points in the plane (Caravello and Tasso, 1999). We used Sardinian municipalities located along transhumance routes and compared the results with the remaining municipalities of the island not involved in transhumance. The coefficient of autocorrelation (Moran's I) is calculated as:

where x represents the surname, w_{ij} is a proximity weight representing the degree of relatedness between location i and j (greater relatedness implies a higher weight); n is the number of locations;

and f_j are the frequency of name x at location i and j respectively. Moran's Index has been widely used in surname analyses (Caravello and Tasso, 1999, 2007; Tasso and Caravello, 2010; Román-Busto et al., 2013). The I coefficient generally varies between -1 (negative autocorrelation) and +1 (positive autocorrelation). In the absence of spatial autocorrelation, the expected value is $-1/(n - 1)$, where n is the size of the sample. A significant negative autocorrelation indicates that at a determined distance the frequencies of a variable are dissimilar, while a significant positive autocorrelation indicates a similarity between populations; a non-significant value shows no relationship between pairs of frequencies of a surname at a certain distance (Sokal and Oden, 1978a).

In this study we selected the 18 most common surnames extracted from the ancient registers of parish censuses of the considered villages. We think that these surnames have a low level of polyphyletism, since they are absent or present at very low frequencies in the other parishes for which it was possible to obtain data from the 19th century.

We explored two different proximity matrices, one based on transhumance regions and one based on non-transhumance regions.

In the transhumance matrix, weights were chosen such that

Instead, matrix is such that

Both, and have zeros in diagonal.

Our goal was to check whether some surnames are clustered in transhumance regions. Thus we tested for independence of name x in transitional regions.

Results

Table 2 shows the most common surnames originating in Barbagia di Belvì, derived from data of the 19th century *Status Animarum*, and the relative frequencies in the historical-geographical areas involved in transhumance. Figure 3 shows where these frequencies are higher (dark areas) or lower (white areas).

Aritzo 1840	a1	Belvi 1993	b2	Desulo 1994	d3	Tonara 1811	t0
Aritzo 1994	a2	Desulo 1816	d0	Gadoni 1815	g0	Tonara 1840	t1
Belvi 1815	b0	Desulo 1840	d1	Gadoni 1840	g1	Tonara 1994	t2

Figure 4 illustrates the relationships among the villages of Barbagia di Belvì and their variations in time. The populations are clearly differentiated on the scatter plot and each of them maintains its specific identity in time. The first dimension separates Aritzo and Belvì from Desulo and Tonara, while Gadoni occupies a central, intermediate position. Desulo and Tonara form a closed cluster without differentiation in time; they are the villages with the most homogeneous structure of surnames. Population growth in the first half of the 20th century seems not to have changed the surname structure of the two villages. This was probably because of their greater geographical isolation due to their higher altitude (*ca.* 900 m a.s.l.). The other three villages exhibit two small distinct clusters, one including the 19th century populations and the other the 20th century

populations. This indicates that changes have occurred in the interval between the surveys. Nevertheless, these villages maintained their specificity of surname structure, since they are differentiated from each other on the basis of both surveys (19th and 20th centuries). The temporal differentiation observed in the other three villages indicates that the isolation of Desulo and Tonara continued while the other three villages tended to change, moving away from the other ones that represent the most isolated part of the Barbagia di Belvì.

Table 3 shows the values of Moran's I with . Note that target surnames such as "Arangino", "Castangia", "Casula", "Onano", "Peddio", "Polla", "Sau", "Todde" and "Zucca" have significant Moran's I positive autocorrelation. These results indicate that those surnames are clustered in the transhumance regions. In particular "Arangino" and "Onano" have high values of the index, clearly clustered in the transhumance path, which is consistent with Figure 3.

Discussion

Data on classical genetic markers (Cavalli-Sforza et al., 1994; Vona, 1997), the HLA system (Contu et al., 1992; Lampis et al., 2000; Grimaldi et al., 2001), autosomal markers (Moral et al., 1994; Calò et al., 1998; Battaglia et al., 2003), mtDNA (Barbujani et al., 1995; Morelli et al., 2000; Malaspina et al., 2000; Richards et al., 2000; Fraumene et al., 2003; Falchi et al., 2006) and Y-chromosome polymorphisms (Semino et al., 2000; Scozzari et al., 2001; Ghiani and Vona, 2002; Francalacci et al., 2003; Quintana-Murci et al., 2003; Rootsi et al., 2004; Capelli et al., 2006) show that the Sardinian population (or its subpopulations) has a peculiar genetic structure that clearly differentiates it from the continental European and circum-Mediterranean populations, as well as from the other populations that currently constitute Italy. Moreover, Sardinia is characterized by specific autochthonous surnames (Lucchetti et al., 1996).

The genetic differences between Sardinians and the other Mediterranean and European populations are very likely due to the upper Paleolithic settlement of the island (Chikhi et al., 2002; Vona and Calò, 2006; D'Amore et al., 2010), its geographical isolation and, despite the many colonizations, the marginal position of the island with respect to mainstream economic development (Le Lannou, 1941; Sanna, 2006). Therefore, the Sardinian people, considered as a whole or as sub-populations, are very distinct among European populations. Nevertheless, the Sardinian population exhibits microgeographical heterogeneity (Vona and Calò, 2006). In fact, various authors have found marked variability within Sardinia (Piazza et al., 1985; Porcella and Vona, 1987; Ulizzi et al., 1988; Cavalli-Sforza et al., 1994; Vona, 1997; Cappello et al., 1996; Calò et al., 1998; Vona and Calò, 2006), leading to a mosaic genetic structure of the Sardinian population, often with different patterns according to the considered genetic markers. Regarding the debate about the heterogeneity of Sardinian populations, it is interesting that the Y-chromosome haplogroup that particularly characterizes the Sardinians with respect to other European and circum-Mediterranean populations (I2a2, M26) is distributed almost uniformly throughout the island (Zei et al., 2003). However, Zei et al. (2003) found that this genetic marker showed high heterogeneity among the three zones that they considered (northern, central-eastern and south-western) when the samples were formed on the basis of the origin of the surnames rather than the zone of residence. Hence, surname analysis is an excellent tool to validate the genetic relationships among populations.

Therefore, Sardinians are heterogeneous in relation to the specific history of the communities living in the island's different historical-geographical zones and also to the isolation of the mountain zones

from those of the plains. In particular, Barbagia di Belvì exhibits isonymic variability in relation to the geographical position of its villages.

Comparison of the single villages indicates that they are different from each other and the differentiation persists over time, so that the same village maintains its identity over the centuries: evidently, the geographical dimension and the local peculiarities are predominant. This is especially true for the two most isolated villages (Desulo and Tonara) but it also holds for the other villages, perhaps more open to migratory exchanges (Aritzo, Belvì, Gadoni), although they became differentiated over time while maintaining their diversified characterization.

Therefore, our results indicate that transhumance from the mountainous center to the southern lowlands and the recent internal migrations (Sanna, 2006) resulted in an appreciable flow of surnames toward the villages of the southern plains. Likewise, there has been a substantial gene flow between the mountain villages and those of the plains. In addition, the historical and geographical areas of the mountains have retained their specific surname identities, which strongly differentiate them from each other.

Nevertheless, we must consider the possible effect on the results of so-called virilocal marriages, i.e. the custom of celebrating the marriage in the village of the bride and then living in the village of the bridegroom (Sanna et al., 2004, 2006). Hence the children of parents who have followed the practice of virilocal marriage will bear the surname of the father, who remains to live in his native village. The maiden surnames of brides who migrate from the villages of Barbagia leave no traces in their native villages. It is also true, however, that marriages are not only exchanges of surnames and therefore of genes, but also occasions of cultural exchanges.

The genetic structure simulated by surnames indicates continuity between the populations of the villages of the southern lowlands and the populations of the mountain villages of the central area of Sardinia. Moreover, the latter differ according to the historical-geographical zones to which they belong; in view of their positions on the nmMDS plot, the villages of Barbagia di Belvì are differentiated from each other.

The results suggest that there has been appreciable admixture between the Sardinian populations of the central mountains and those of the southern lowlands.

In view of the similarities found between the surnames of the populations of the central area of the island and those of the lowlands, future research should address the genetic relationships among these Sardinian individuals. For this purpose, studies should include individuals whose origin is known and for whom a genealogical reconstruction is possible.
