ABSTRACT

Context. Most active galactic nuclei (AGNs) are radio quiet (RQ), with radio emission that may arise from star-formation activity, AGN-driven winds, weak jets, and coronal activity. Disentangling these mechanisms is challenging and requires detailed multi-wavelength investigations, but it is crucial for quantifying AGN feedback in galaxy evolution.

Aims. We present a detailed radio investigation of 22 X-ray-selected AGNs in the Supermassive Black Hole Winds in X-Rays (SUBWAYS) sample ($L_{bol} \approx 10^{44.9-46.3}$ erg/s, $z=0.1-0.5$), selected to systematically search for ultra-fast outflows (UFOs). The UFOs are detected in $\sim 30\%$ of the targets, with measured velocities and kinetic luminosities, making the sample particularly well-suited for investigating the role and signatures of multi-scale outflows at different frequencies.

Methods. We built the radio spectral energy distribution of the sources complementing our proprietary data, collected with the JVLA at 1.5 and 6 GHz, with images from LoTSS (145 MHz) and other publicly available radio surveys between 150 and 1400 MHz.

We investigated the role and occurrence of the aforementioned mechanisms, with particular interest in outflows and their possible relation to UFOs. To achieve this, we combined information on spectral indices, luminosities, and morphologies of radio emission with properties derived in other wavebands, such as the star formation rate, the X-ray luminosity, the Eddington ratio, or the UFO kinetic luminosity.

Results. All sources are detected and are mostly consistent with RQ AGNs. For $\sim 80\%$ of the sources, the data suggest the presence of an outflow (wind or weak jet). Interestingly, our results indicate that AGNs with UFOs tend to have larger radio extension and a steep radio spectrum consistent with outflows. Moreover, the radio emission of the six UFO hosts is consistent with predictions from wind-driven shock models, possibly indicating a direct connection between the two phases. Alternatively, this may simply reflect physical conditions that favour the production of both phenomena.

Key words. radio emission – AGN – feedback – SED – VLA – LOFAR

1. Introduction

Accretion onto supermassive black holes (SMBHs) can light up the nuclear regions of galaxies, giving rise to the so-called active galactic nuclei (AGNs), which are among the most energetic objects in the Universe (see Kormendy & Ho 2013 and Alexander et al. 2025 for reviews). Active galactic nuclei have been shown to inject significant amounts of energy and momentum into their surroundings from parsec to Mpc scales. This occurs via multiple channels, including direct radiation (e.g. Ciotti et al. 2010), jets of relativistic plasma (e.g. Fabian 2012), and massive multi-phase gas winds (e.g. Crenshaw et al. 2003). In particular, through the interaction with the interstellar medium (ISM), powerful AGN-driven outflows, in the form of winds or jets, have proven to be capable of reproducing the scaling relations between SMBH mass and galaxy properties (Cattaneo et al. 1999; Kauffmann & Haehnelt 2000; King & Pounds 2015; King et al. 2005; Gaspari et al. 2020; King & Pounds 2015; Fabian 2012). While synchrotron emission from powerful relativistic jets dominates the radio luminosity only in a minority of AGNs, classified as radio loud (RL, $L_{6GHz} = 10^{23-27}$ W/Hz), the majority falls into the radio quiet (RQ; $L_{6GHz} = 10^{21-23}$ W/Hz) category, where the origin of radio emission is still debated. In RQ

AGNs, radio emission can arise from a plethora of processes, possibly overlapping, including AGN-driven winds, weak jets, coronal activity, and star-formation activity (see Padovani 2017; Panessa et al. 2019 for extensive reviews). Disentangling these mechanisms and understanding how the energy they release couples with the ISM is challenging and requires detailed spectral and morphological analysis. However, obtaining observational constraints is crucial for modelling AGN feedback and galaxy evolution.

The AGN-driven winds are indeed detected in any gas phase, at different ionisation states, velocities, and distances from the inner SMBH. These range from sub-relativistic ($0.1 - 0.25 c$), highly ionised, ultra-fast outflows (UFOs), arising at few gravitational radii (e.g. Chartas et al. 2002; Tombesi et al. 2010; Pounds 2014; Tombesi et al. 2015; Matzeu et al. 2023; Gianolli et al. 2024), down to the slower ($\sim 500 - 2000$ km/s) outflows detected on kpc scales, in the atomic and molecular gas phases (e.g. Zakamska & Greene 2014; Morganti et al. 2016, and see Cicone et al. 2018 for a review). In luminous RQ AGNs, it has been proposed that the shocks generated by radiatively driven winds can accelerate electrons, producing synchrotron radio emission on scales larger than 100 pc with $\nu L_\nu \sim 10^{-5} L_{AGN}$ (Zakamska & Greene 2014; Nims et al. 2015). However, how the different

Fig. 1. Bolometric luminosity as a function of redshift. The grey contours highlight the AGNs of Yamada et al. (2024a, Y24), the red ones are the data from Laor & Behar (2008, LB08), and those in purple the data from Panessa & Giroletti (2013, PG13). We choose LB08 and PG13 as a comparison for the study of the X-ray-radio luminosity correlation. Then we plot the objects in the SUBWAYS sample (blue empty dots) and a comparison sample from Tombesi et al. (2010, T10, black empty diamonds). UFO hosts are marked by stars and triangles in SUBWAYS and T10 respectively.

wind phases are connected to each other is still poorly understood.

Recent observations also showed that low-luminosity ($\log P_{1.4\text{GHz}} < 10^{24}$ W/Hz) galaxy-scale radio jets, which are much more common than their high-power counterparts (Mauch & Sadler 2007; Sabater et al. 2019; Venturi et al. 2021; Speranza et al. 2022; Murthy et al. 2022; Cresci et al. 2023; Ulivi et al. 2024), remain trapped in the ISM for longer, affecting the surrounding medium over a large volume (e.g. Bicknell 1994; Jarvis et al. 2019; Mukherjee 2025). Such low-power jets can still account for the radio emission observed in RQ AGNs. However, AGN winds and jets can coexist (e.g. Tombesi et al. 2012; Mestici et al. 2024), making it complicated to understand their potential causal connection. In addition, recent work discusses the possibility that UFOs can accelerate ultra-high-energy cosmic rays. If such associations are confirmed, they would provide further motivation to test whether X-ray UFOs correlate with extended non-thermal radio emission (Karwin et al. 2023; Ehlert et al. 2025).

The current literature providing a detailed investigation of the radio emission in UFO hosts has been largely limited to single-object analyses or archival studies (e. g. Falcke et al. 1998; Tombesi et al. 2010, Tombesi et al. 2012; Tombesi et al. 2014; Morganti 2017; Giroletti et al. 2017; Wang et al. 2021; Longinotti et al. 2023; Maksym et al. 2023; Zanchettin et al. 2023; Yamada et al. 2024b).

In this paper we present the analysis of new Jansky Very Large Array (JVLA) observations, obtained at 1.5 and 6 GHz of 22 quasars belonging to the Supermassive Black Holes Winds in X-rays (SUBWAYS) sample. By combining JVLA data with radio observations from additional surveys, together with the wealth of multi-wavelength data available for the SUBWAYS sample, we investigate the origin of the radio emission (star

formation, coronae, or outflows) and characterise the contribution of AGN-driven outflows¹, with particular emphasis on UFO hosts. This work constitutes the first systematic analysis that exploits dedicated follow-up observations for a sample of RQ AGNs with detected UFOs.

This paper is organised as follows: in Sect. 2 and 3 we describe the sample and how the data have been collected and reduced; in Sect. 4 and 5 we discuss the results and consider the potential origins of the radio emission, investigating how the radio properties of the sample relate to those derived in other wavebands. In Sect. 6 we draw our conclusions.

Throughout this work, a standard Lambda cold dark matter (Λ CDM) cosmology has been adopted, with $H_0 = 71 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_\Lambda = 0.73$, and $\Omega_m = 0.27$. The uncertainties are always reported at 1σ .

2. The sample

SUBWAYS was born with the aim of increasing the number of known UFO hosts with multi-wavelength observations. The whole project is based on a large XMM-Newton campaign (~ 1.5 Ms of observing time in 2019-2020; Brusa et al. 2022) of a sample of 17 (plus five collected from the XMM archive with comparable spectral quality) X-ray selected AGNs (mostly Type 1 quasar (QSO), with $\log(M_{\text{BH}}/M_{\text{odot}}) = 7.46 - 9.22$ and $-1.92 < \log \lambda_{\text{Edd}} < 0.35$), chosen at redshift $z=0.1-0.5$ and with bolometric luminosity $L_{\text{bol}} \approx 10^{44.9-46.3} \text{ erg/s}$. In Table 1 we list the 22 sources belonging to SUBWAYS with their basic properties. Sources with a UFO detection in the confidence interval $\geq 99\%$ are placed above the horizontal line. The unprecedented quality reached by XMM-Newton spectra allowed a detailed investigation of under-explored ranges of redshift and luminosity in UFO studies. From the main analysis of the XMM-Newton observations, Matzeu et al. (2023, Paper I) reported, in seven of the 22 AGNs ($\sim 30\%$), significant detection of absorption lines corresponding to high column density, highly ionised iron with outflow velocities in the range $-0.3 \leq v_{\text{out}}/c \leq -0.05$, consistent with the expectations for UFOs. Complementary UV imaging data have been obtained with *Hubble* Space Telescope (HST; PI: G. Kriss), but no counterpart for the UFO was found (Mehdipour et al. 2023, Paper II). These results could be attributed either to an excessively high ionisation state or to a low covering fraction of the UV-emitting source. Moreover, correlations of SUBWAYS UFO parameters with X-ray luminosity are found to be much stronger than those with the UV luminosity (Gianolli et al. 2024, Paper III), suggesting that the innermost regions of the AGNs are more significantly involved than the accretion disk in powering sub-relativistic winds. In fact, though for four objects with UFO detection thermal pressure could in theory launch the outflow, it cannot explain the outflow velocity of UFOs, suggesting that a combination of magnetically and radiatively driven processes is needed (see Fig. 11b of Paper II).

Figure 1 shows the bolometric luminosity (L_{bol}) redshift plane of the SUBWAYS sample in the context of literature samples of detected X-ray outflows: the one compiled by Yamada et al. (2024a, Y24), which includes 132 AGNs at $z=0-4$, and encompasses 93 UFO hosts known so far (including the SUBWAYS sample) and the one from Tombesi et al. (2010, T10, included in Y24 as well), which represents the low-redshift ($z \leq 0.1$) comparison sample used in Paper III and, for consistency, also adopted in this work. The red and purple contours

¹ Throughout the paper, when we do not distinguish between winds and jets we refer to them more generally as outflows.

Notes. Column 1: Reference label. Column 2: Target name. Column 3 and 4: Coordinates. Column 5: Redshift. Column 6: Luminosity distance. Column 7: Bolometric luminosity. Column 8: X-ray luminosity (derived from *XMM-Newton* analysis, Paper I). Column 9: SMBH mass in units of solar masses. Column 10: Eddington ratio (Paper I). Column 11: Outflow velocity in units of c (Paper III) for the UFO detected with confidence interval $\geq 99\%$ (Paper I). PG1202+281 was not observed by JVLA. For completeness we list its properties here, even though it was not analysed in this work. The UFO subsample is shown before the horizontal line.

instead show the location in the $L_{\text{bol}} - z$ plane of the samples of Laor & Behar (2008) and Panessa & Giroletti (2013), which we chose as a comparison for the study of the correlation of X-ray and radio luminosity.

3. Data

3.1. JVLA data reduction

We made dedicated observations of the sample with the JVLA interferometer between August 2020, May 2023 (PI: F. Panessa), and January 2026 (PI: E. Amenta) in B configuration ($b_{\text{min}} \sim 0.21$ km, $b_{\text{max}} \sim 11.1$ km). This set-up has, for the purposes of this work, the right trade-off in terms of maximum and minimum baseline length, providing indeed both good resolution and good sensitivity, necessary for a meaningful morphological analysis.

The data were collected using the L- and C-band receivers (1.5 and 6 GHz respectively), with 30 minute and 5 minute observations of each target, respectively. Taking into account a 50% overhead for each observing block, which includes telescope initial set-up, phase and amplitude calibration, and slewing between sources, the total observing time is equal to 18.5 observing hours in the L band and 2.88 in the C band. The predicted resolution is 4.3'' at 1.5 GHz and 1'' at 6 GHz, with 1'' being $\sim 2 - 4$ kpc at the redshift of our sources.

For all observing blocks, we downloaded the datasets calibrated by the observatory pipeline², then checked the goodness of automatic calibration and, if necessary, improved target flagging with AOFlagger³ (Offringa 2010).

The imaging was performed with the Common Astronomy Software Applications package (The CASA Team et al. 2022 CASA 6.6.3.22 version⁴) task `tclean`, weighting the visibilities with the Briggs scheme (Briggs 1995), with weighting parameter as listed in Table A.1. We based the flux-density scale on measurements of VLA primary amplitude calibrators by Perley & Butler (2013). Whenever the noise displayed a non-uniform pattern, before attempting the self-calibration, we tried imaging the data with `w-stacking clean` (WSClean)⁵ (Offringa et al. 2014) and this often improved the results. The images produced with this software are labelled * in Table A.1. This was not sufficient for two of the targets, PG1425+267 and HB891529+050, for which we performed one round of phase self-calibration within CASA.

All parameters relative to the final images are listed in Table A.1. The typical resolutions are $\theta_{1.5\text{GHz}} \sim 4''.5$ and $\theta_{6\text{GHz}} \sim 1''$, with a median noise equal to $\sigma_{\text{rms}}=0.02$ mJy beam⁻¹ and 0.012 mJy beam⁻¹ at 1.5 and 6 GHz respectively.

3.2. Complementary data

To investigate the morphology of the sources at different frequencies and their broadband radio spectral shape, we combined the aforementioned JVLA 1.5 and 6 GHz simultaneous data with the LOw Frequency ARray Two-metre Sky Survey (LoTSS; Shimwell et al. 2017; Shimwell et al. 2022) data. The aim of LoTSS is to survey the whole northern sky at 145 MHz with a resolution of $\sim 6''$, comparable to that of the proprietary data, and a sensitivity ~ 0.10 mJy beam⁻¹. There are LoTSS mosaics

² VLA CASA Calibration Pipeline 5.6.2

³ AOFlagger documentation

⁴ CASA documentation

⁵ WSC version 3.1

Fig. 2. Images of the ‘multi-component’ sources. Colours at 6 GHz with $\sigma_{rms} \cdot [-3, 3, 6, 12, 24, 48, 96]$ contours at 1.5 GHz (white) and 145 MHz (green). The beams are shown in the bottom-left corner of each panel. Labels A, B, and C mark distinct radio components: A denotes the nuclear (core) component spatially coincident with the optical AGN position, while B and C denote spatially-separated extranuclear components (i.e. features that are not coincident with the optical/IR nucleus and that extend beyond the host’s optical light profile) likely related to AGN outflows.

available for 18 of 22 targets (the remaining four are too far south to be observed with LOFAR); in particular, 11 of the mosaics are currently released within the LoTSS collaboration in DR3 (Shimwell et al. 2026).

To further sample the 145 MHz–6 GHz frequency range and test temporal variability, we also considered images from other surveys, which we list here together with their main properties:

- TGSS (TIFR Giant Metrewave Radio Telescope) at about 150 MHz (ADR1; Intema et al. 2017)⁶ with a 2'' resolution and a median noise of 3.5 mJy beam⁻¹ (Intema et al. 2017). We rely on TGSS for the four sources located too far south to fall into the LoTSS footprint.

- RACS - low Data Release 1 (Rapid ASKAP Continuum Survey DR1) images at 888 MHz have a common resolution of 25'', with a uniform sensitivity of about 0.25 mJy beam⁻¹ (McConnell et al. 2020; Hale et al. 2021). The RACS cutouts are available for 15 targets.

- FIRST (Faint Images of the Radio Sky at Twenty-cm) Survey is a survey done with VLA in B configuration at 1.4 GHz, with a 5'' resolution and median noise of 0.15 mJy beam⁻¹ (Becker et al. 1995). Among the objects belonging to the SUBWAYS sample, four are not covered by FIRST.

- VLASS (Very Large Array Sky Survey) is conducted by the VLA in B configuration, with multi-epoch observations at 3 GHz, separated by approximately 32 months. Observations are available for three epochs, with a sensitivity ~ 0.16 mJy beam⁻¹ and a resolution $\sim 2.4''$ (Lacy et al. 2016; Lacy et al. 2020; Gordon et al. 2021). Cutouts of the three epochs are available for all objects, but, unless otherwise specified, we refer only to the third because it is the most recent one.

A more in-depth discussion of the use of these data can be found in the following section. The final images are displayed in Appendix B with L-band white contours superimposed on the C-band colours. The green contours belong to the LoTSS images.

4. Results

4.1. Detection rates and morphologies

All sources (22/22, 100%) are detected at 1.5 and 6 GHz, and 17/18 ($\sim 94\%$) are detected at 150 MHz. Due to the worse

resolution and/or sensitivity, in the remaining complementary data the fraction of detected objects decreases resulting in 11/15 ($\sim 73\%$), 13/18 ($\sim 72\%$) and 13/22 ($\sim 59\%$) at 888 MHz, 1.4, and 3 GHz, respectively. This shows the importance and need for dedicated observations for such faint objects.

A compact emitting region, spatially coincident with the optical centre of the AGN, is detected for all of the sources at both 1.5 and 6 GHz, with a signal-to-noise ratio larger or equal to 6 in all cases (see Appendix A). An exception is the 1.5 GHz image of PG1352+183, where the emission is detected at $3\sigma_{rms}$ only (see Appendix B). For the four targets not covered by LoTSS we derive upper limits from TGSS (Col. 3 of Table 3, more comments in Sect. 4.5).

We provide a morphological classification of the sources by comparing the highest (6 GHz) frequency proprietary images and the lowest (145 MHz) frequency LoTSS one, which may be sensitive to different components. To do so, for individual components, we fit a Gaussian within the $3\sigma_{rms}$ contours in CASAvierwer at both frequencies. A deconvolved value is given by gaussfit, to which the algorithm already associated uncertainty. If the source is found to be resolved, this approach provides the least instrumentally biased measurements, which is important for compact emitting regions, as in the case (of the majority) of this sample.

With this approach 11/22 (50%) sources are classified as unresolved at all frequencies. In these cases, we associate with their extension an upper limit given by the major axis of the restoring beam. Only one source (PG1427+480), appears to be unresolved at 1.5 GHz (L band) and 6 GHz (C band), but shows extensions at 150 MHz, thus we classify it overall as resolved (Fig. 3). Moreover, at a distance $\sim 1.4'$ in the north-east direction of PG1427+480, some very faint extended emission is detected in the LoTSS image. In Fig. 3 we plot in green the contours of the low resolution LoTSS image ($20 \times 20''$) where the detection of such features reaches $9\sigma_{rms}$. There is no clear morphological connection with the target nuclear emission, and overlays with the optical/IR surveys reveal some background objects in the same region. However, there is no clear optical/IR identification, leaving open the possibility that the emission is associated with PG1427+480.

All objects with an angular size larger than the beam major axis are resolved and classified as extended. In all the targets that belong to this class, the compact central emitting source is

surrounded by extended emission. Among these, three sources (PG0804+761, 2MASXJ1653+23, and PG1425+267) exhibit multiple components (Fig. 2), where some features are well distinguished from the compact central structure, unambiguously extended for several arcseconds, and are not associated with neighbouring sources (see also Appendix B). We measure the maximum extension of these three targets with the ruler tool in CASAviewer, taking as a reference the $3\sigma_{rms}$ contours.

At both 1.5 and 6 GHz 10/22 ($\sim 45\%$) targets belong to the class of extended sources, with three of them being multi-components ($\sim 14\%$ of the total sample). In LoTSS images 11 objects are resolved with the same number (3) of multi-components seen by JVLA. The results are summarised in Table 2.

We also note that there are two targets that show adjacent radio emission, namely PG0947+396 and PG0953+414 (see Appendix B). However, further multi-wavelength investigation reveals that the emission is unrelated to the targets but is instead associated with an edge-on spiral galaxy in the first case, and a blazar, SDSSJ095651+411558 at $z \sim 0.6$, in the second.

4.2. Flux densities

For unresolved sources, we extracted the integrated flux densities within the $3\sigma_{rms}$ contours from the images at their original resolution, at all frequencies, using the task `imstat`.

For extended sources instead, we first match the image resolution of the proprietary data to derive consistent measurements that can be used to compute spectral indices reliably between 145 MHz and 1.5 GHz and between 1.5 and 6 GHz. We note that all sources, even when resolved, except for PG1425+267,

Fig. 3. Image of PG1427+480, showing the extended emission detected in the north-east direction of the target, which is located in the lower-right region of the image. Colours at 6 GHz with σ_{rms} \cdot $[-3, 3, 6, 12, 24, 48, 96]$ contours at 1.5 GHz (white) and 145 MHz ($6''$ in green, $20''$ in cyan). The beams are shown in the bottom-left corner of the panel. The black cross marks the optical position of the AGN.

have sizes smaller than the largest C-band angular scale recoverable by the instrument ($29''$), ensuring no flux loss. Hence, only for PG1425+267 we set a cut in baseline length during imaging ($b_{min} \sim 2585\lambda$), so that all data are sensitive to the same scales of emission at both frequencies (see Table A.1).

For all the extended targets, we first created new images at 6 GHz with a natural weighting, then smoothed the outcomes with the task `imsmooth` to match the beam at 1.5 GHz. The final

Table 3. Integrated flux densities used in this work and their associated uncertainties.

Notes. Column 1: Target name. Columns 2–8: Integrated flux densities from TGSS (150 MHz), LoTSS (145 MHz), RACS (888 MHz), FIRST (1.4 GHz), JVLA L-band (1.5 GHz), VLASS (3 GHz), and JVLA C-band (6 GHz). The UFO subsample is shown before the horizontal line.

images at 6 GHz have $\theta_{6\text{GHz}} \sim 4'' - 5''$, for the targets labelled with † in Table A.1. The flux densities are then measured from these images following the $3\sigma_{rms}$ contours. The same approach is used to extract flux densities from complementary surveys. We note that the resolution of the archival images from FIRST and VLASS is similar enough to LoTSS and the proprietary data to allow for a qualitative comparison. Lastly, despite the much worse resolution, RACS data can be useful in reconstructing the overall SED (spectral energy distribution) shape. Further discussion on this can be found in Sect. 4.5.

The uncertainty associated with the integrated flux density F_ν is computed as

$$\sigma_{F_\nu} = \sqrt{(\delta_{F_\nu} \cdot F_\nu)^2 + (\langle \sigma_{rms} \rangle_\nu \cdot \sqrt{n_{beams}})^2}, \quad (1)$$

where δ_{F_ν} is the fraction of uncertainty associated with the flux density calibration, dependent on instrument and frequency, $\langle \sigma_{rms} \rangle_\nu$ is the average noise at frequency ν , and n_{beams} the area encompassed by the source in the beam unit. We used the standard JVLA flux density scale calibration uncertainty (5%) for the proprietary data, FIRST and VLASS, while for LoTSS images we used the standard flux density calibration uncertainty for the DR2 $\delta_{F_\nu} = 15\%$. For RACS images we assumed a flux density scale calibration uncertainty of 5%. All measurements are reported in Table 3. The tabulated VLASS flux density is measured from the third and most recent epoch.

To compute the σ_{F_ν} of unresolved objects, n_{beams} is equal to unity, while in all the other cases it is the area used for measure-

ment in units of beam. Whenever the target is undetected upper limits are derived as $3\sigma_{rms}$.

4.3. Spectral indices

To study the radio spectral shape, we computed the slopes of the spectra between 145 MHz and 1.5 GHz (α_{1500}^{145}) and between 1.5 and 6 GHz (α_{6000}^{1500}).

The spectral index is computed as

$$\alpha_R = -\frac{\ln(F_{\nu_2}/F_{\nu_1})}{\ln(\nu_2/\nu_1)} \quad \text{where } F_\nu \propto \nu^{-\alpha_R} \quad (2)$$

with associated uncertainty

$$\sigma_{\alpha_R} = \frac{1}{\ln(\nu_2/\nu_1)} \sqrt{\left(\frac{\sigma_{F_{\nu_1}}}{F_{\nu_1}}\right)^2 + \left(\frac{\sigma_{F_{\nu_2}}}{F_{\nu_2}}\right)^2}, \quad (3)$$

where ν_1 and ν_2 are, respectively, the lower and higher frequency between which the spectral slope is computed.

In the left panel of Fig. 4, we show the distribution of the spectral index; more specifically, the filled histogram represents the distribution of the values computed between 1.5 and 6 GHz, while the barred one represents the distribution between 145 MHz and 1.5 GHz. The upper limits are shown in grey. We note that the values of α_{6000}^{1500} derive from simultaneous observations, thus they constitute a robust view of the spectral slope at those frequencies, avoiding potential artificial steepening and/or flattening due to strong variability.

Fig. 4. Left: Spectral index distribution of the sample. The filled histogram represents the values computed between 1.5 and 6 GHz, while the barred one those computed between 145 MHz and 1.5 GHz. Middle: Histogram comparing the total radio luminosities of the sample. Blue: 145 MHz. Violet: 1.5 GHz. Green: 6 GHz. The upper limits at 145 MHz have been excluded. Right: Radio loudness parameter distribution of the sample. The convention followed is $R_X = \log(L_R(6cm)/L_X(2-10KeV))$ (Terashima & Wilson 2003). The filled histogram represents the values of R_X computed for the UFO hosts, and the barred histogram those derived for the non-UFO hosts. The vertical red line marks the -4.5 limit set by Terashima & Wilson (2003). RQ AGNs tend to dominate the sample, while RL AGNs represent only a small fraction, specifically 6/21 with the original limit $R_X = -4.5$.

The spectral index of the nuclear and extranuclear components of 2MASXJ1653+23 and PG0804+761 are reported separately in Table 4. Overall the spectral index distributions span from 0.15 up to 0.68 at lower frequencies, and from -0.17 up to 0.99 at higher ones, with median values 0.57 ± 0.05 and 0.45 ± 0.08 for α_{1500}^{145} and α_{6000}^{1500} respectively, computed taking into account the upper limits through a Kaplan-Maier (KM) survival analysis⁷.

4.4. Radio luminosities and radio loudness

We calculate the characteristic monochromatic radio powers at 145 MHz, 1.5, and 6 GHz, using the following expression

$$L_\nu = 4\pi D_L^2 (1+z)^{(\alpha_R-1)} F_\nu, \quad (4)$$

where F_ν is the flux density, D_L the luminosity distance at redshift z (see Table 1), and α_R the radio spectral index, which is substituted with α_{145}^{145} when computing L_{145MHz} , while α_{6000}^{1500} is preferred for estimating both $L_{1.5GHz}$ and L_{6GHz} . An uncertainty is associated according to the following

$$\sigma_{L_\nu} = 4\pi D_L^2 (1+z)^{(\alpha_R-1)} \sqrt{(F_\nu \ln(1+z) \sigma_{\alpha_R})^2 + \sigma_{F_\nu}^2}. \quad (5)$$

The values are reported in Table 4 and shown in the histograms in the middle panel of Fig. 4. The characteristic spectral luminosities range between $22.60 < \log L_{145MHz} < 27.06$ W/Hz at the lowest frequency, and between $21.63 < \log L_{6GHz} < 25.51$ W/Hz at the highest, with median values 23.28, 22.70, 22.43 W/Hz at 145 MHz, 1.5 GHz, and 6 GHz, respectively.

In addition, taking into account the entire radio emission, we compute the radio loudness parameter $R_X = \log(L_R(6cm)/L_X(2-10keV))$ (Terashima & Wilson 2003) and report the values in Table 5. Assuming $R_X = -4.5$ as the transition between the RQ and RL regime, following Terashima & Wilson (2003), we find that RQ AGNs tend to dominate the sample, while RL AGNs represent only a small fraction (six out of 22). However, the sample overall spans the region around the

traditional boundary value (red line in Fig. 4, right). This supports the growing difficulty in setting a well-defined difference between RQ and RL AGNs, since the probability distribution of R_X typically does not show strong signs of bi-modality (e.g. La Franca et al. 2010).

4.5. Radio spectral energy distributions (SED)

To investigate the broad band SED we combined the values reported in Sect. 4.2 with measurements from TGSS, RACS, FIRST, and VLASS (see Appendix B). We plotted as blue dots the data used for computing the spectral indices (the ones from LoTSS and the proprietary data) and connected them with a solid line when representing actual detections. The grey dots represent all the remaining archival data from RACS, FIRST, and VLASS. In case no LoTSS mosaics are available, we add the TGSS upper limit as a grey dot at 145 MHz. The VLASS flux densities, as mentioned above, are from epoch 3, unless they show significant offset with respect to the computed α_{6000}^{1500} ; in such cases, we also plot all available epochs as crosses.

We stress that the newly added flux densities are derived from images with resolutions similar to the proprietary data, with the exception of RACS (25''). However, we verified from high-resolution images at both frequencies higher and lower than that of RACS that a 25'' does not encompass unwanted extended emission from nearby sources. We also verify that the images are sensitive to the maximum source spatial scale. We also report in the legend of each SED in Appendix B the computed values of α_{1500}^{145} and α_{6000}^{1500} , and when consistent with each other within the uncertainties, we fit all the SED points with a single power-law of index α_{fit} . For PG0804+761 and 2MASXJ1653+23 we also show the SED of each component separately (labelled as A, B, and C in Fig. 2).

The flux densities are integrated, at all frequencies, on the whole extension of the targets, including as a consequence all the extended features and the resolved components, so that the physical interpretation of the spectral signatures presented in the following section takes into account the potential superposition of different contributions from different regions. Moreover, only the proprietary data are simultaneous; therefore, we cannot exclude that variability may affect some of our conclusions.

⁷ The Kaplan-Meier estimator is a non-parametric method adapted to estimate the cumulative distribution function (CDF) for data containing non-detects (left-censored data). The median survival time is estimated as the point where the CDF drops to 0.5.

Notes. Spectral indices of the single extranuclear components of multi-component sources are reported as well. Column 1: Target name. Column 2: Redshift. Columns 3–4: Spectral index between 145 MHz and 1.5 GHz and between 1.5 and 6 GHz, respectively. Column 5: Spectral curvature. Columns 6–8: Logarithmic radio luminosities at 145 MHz, 1.5 GHz, and 6 GHz. The UFO subsample is shown before the horizontal line.

Indeed, in some objects, variability is suggested by the observed discrepancy between the flux densities measured between FIRST and JVLA proprietary data (e.g. PG1427+480 and PG1435-067 with FIRST measurements being a factor of ~ 3.3 and ~ 2.8 higher, respectively; see [Appendix B](#)). In such cases, as a further test, we plot all three VLASS epochs.

5. Discussion

In this section, we investigate the main mechanisms at the origin of the radio emission and integrate our results into the relevant scientific framework. We note that, in more than one case, the SED are best interpreted by a superposition of different processes. However, here we aim at distinguishing the dominant one rather than doing an SED fitting decomposition. In the following, we focus mainly on the general view; for details on single objects we refer to [Appendix B](#).

5.1. Morphology and linear sizes

The morphology and linear size are powerful tools to distinguish the origin of the radio emission: coronal emission coming from sub-pc scales is expected to be compact and unresolved, and star-forming regions can extend up to the same scales as the host

galaxy. Only outflows are capable of going beyond the stellar body of the host. We convert the angular sizes (see Cols. 3 and 6 of [Table 2](#)) into linear ones (Cols. 4 and 7).

While for unresolved targets the highest resolution of the JVLA at 6 GHz constrains the sizes to linear scales < 1 kpc, all ten targets resolved at all frequencies – six of which have UFOs – display clear extensions on scales ranging from 11 kpc to 1250 kpc (Col. 4 of [Table 2](#)). These extensions suggest that diffuse star formation (SF) and winds and/or jets are present ([Behar et al. 2015](#); [Panessa et al. 2019](#); [Kawamuro et al. 2022](#); [del Palacio et al. 2025](#); [Ricci et al. 2023](#)), although an unresolved coronal component cannot be ruled out (e.g. [Chen et al. 2024](#)).

Interestingly, among these, a giant radio quasar (GRQ; e.g. [Dabhade et al. 2020](#), [Kuźmicz & Jamroz 2021](#)), PG1425+267, is identified. In the original selection, RL AGNs with prominent jets were excluded on purpose; however, the quality of the archival information on PG1425+267 was evidently insufficient to classify it as such. An in-depth discussion on the properties of PG1425+267 is beyond the aims of this work.

Both the other two multi-component sources, 2MASXJ1653+23 (which is a well-studied AGN; [Villar-Martín et al. 2017](#)) and PG0804+761 host a UFO (with $v_{out} \simeq 0.128c$ and $0.108c$, respectively, [Table 1](#)), and show

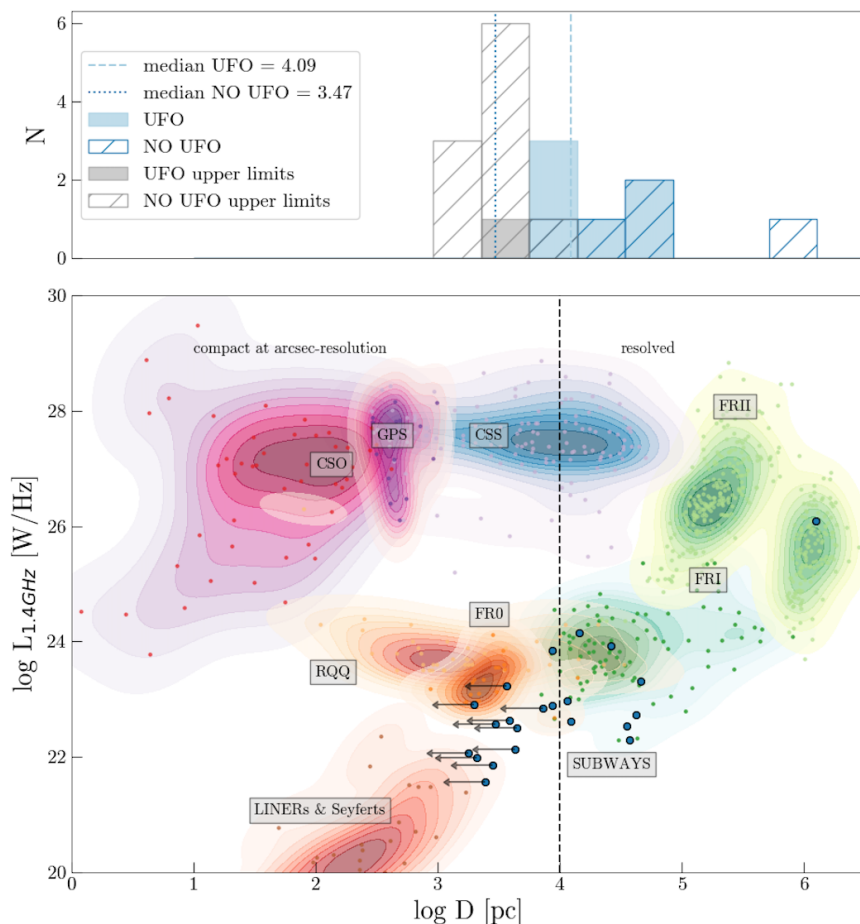

Fig. 5. Radio power at 1.4 GHz versus linear size plot (P-D diagram) for different types of RL and RQ AGNs, adapted from Baldi (2023). Points show individual objects and coloured contours represent a smoothed estimator of source density. The different categories of source shown are: CSO (compact symmetric objects), GPS (GHz-peaked spectrum sources), CSS (compact steep spectrum sources), FRI, FRII, RQ quasars, Seyferts and LINERs, and FR0s. The vertical dashed line roughly marks the separation between resolved and unresolved compact sources based on arcsecond angular resolution. The blue dots represent how SUBWAYS AGNs overlap to LINERs & Seyferts, FRI, FR0s and RQQ. PG1425+267 is a strong outlier, falling on the FRIIs region. Such variety is consistent with the sample being selected based on its X-ray properties. In the upper panel we show the linear size distribution of the sample, with the UFO-subsample (filled histogram) separated from the non-UFO one (barred histogram). The median physical size measured for the UFO subsample is higher (12.35 ± 5 kpc) with respect to the non-UFO one (2.96 ± 1 kpc), potentially supporting multi-phase outflow models (e.g. Crenshaw et al. 2003). Medians are computed taking into account the upper limits through KM survival analysis. Catalogue references: LINERs & Seyferts (Baldi et al. 2018), FR0 (Baldi et al. 2019; Cheng & An 2018); RQQ (Jarvis et al. 2021); GPS (Liu et al. 2007); CSS (Kunert-Bajraszewska et al. 2010); CSO (An & Baan 2012); FRI (Dabhade et al. 2020; Jimenez-Gallardo et al. 2019); FRII (Lao et al. 2024; Fanti et al. 1987).

resolved extranuclear components separated by 45.6 ± 1.1 kpc and 41.81 ± 1.1 kpc, respectively (Table 2).

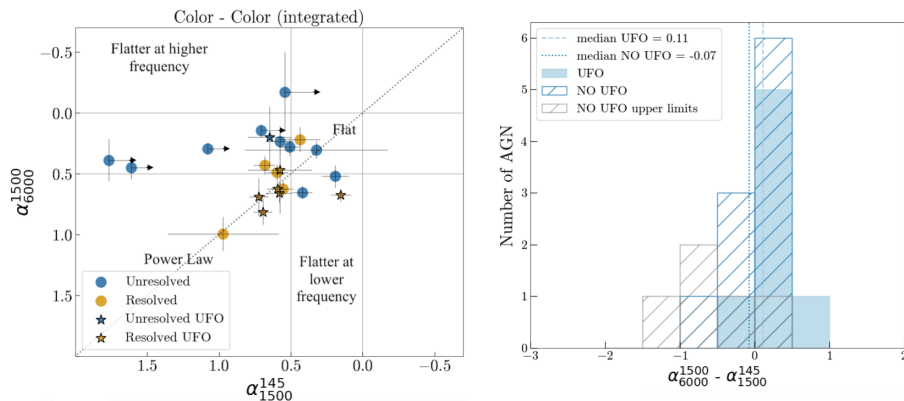

Interestingly, all but one of the seven UFO hosts (PG0947+396) are resolved, suggesting that the radio emission is related to shocks driven by a large-scale outflow, potentially linked to the nuclear wind. A similar connection between extended radio emission and X-ray outflow has been proposed for other RQ objects such as Mrk 34 (Falcke et al. 1998; Maksym et al. 2023), IRAS17020+4544 (Longinotti et al. 2023), and NGC 2992 (Zanchettin et al. 2023). Although with the present sample size the result should be considered tentative⁸, the higher incidence of extended radio morphologies in AGNs hosting a UFO (UFO subsample) with respect to those that do not (non-UFO subsample), suggests a physical connection between extended radio emission and X-ray winds, and favours a scenario in which only a subset of AGNs launch powerful outflows (Tombesi et al. 2010; Tombesi et al. 2012; Paper I; Paper II).

To quantify this, we verified that, using the most representative sizes, measured at 6 GHz for the unresolved objects and at 145 MHz for the resolved ones, the median physical size of the radio emission measured for the UFO subsample (the filled histogram in Fig. 5) is higher (12.35 ± 5 kpc) with respect to that of the non-UFO one (2.96 ± 1 kpc, barred histogram in Fig. 5). However, a log-rank test yields a p-value of ~ 0.52 , indicating that there is no significant difference between the two distributions. Again, larger statistics are needed to confirm or reject this

tentative result. Similarly, the two subsamples do not show any clear bimodality in R_X , with median values equal to -5.11 and -5.35 for the UFO and non-UFO subsamples, respectively, and the p-value $p \sim 0.44$.

By locating the sample in a radio luminosity-linear size (P-D) diagram, as shown in Fig. 5, it is immediately noticeable that SUBWAYS (blue dots) occupies a region wide enough to encompass at least four different classes of objects: classical RQ quasars (RQQ, yellow), low-ionisation nuclear emission-line region galaxies (LINERs; Singh et al. 2013) & Seyferts (brown; Seyfert 1943), low-power Fanaroff-Riley Is (FRI, dark green; Fanaroff & Riley 1974) and Fanaroff-Riley 0 (FR0, orange; Baldi et al. 2016). The only point located in the region occupied by Fanaroff-Riley IIs (FRII; Fanaroff & Riley 1974) is the GRQ PG1425+267, which represents a clear outlier. The sample shows how an X-ray selection picks up a variety of radio-emitting AGNs; therefore, we expect a non-homogeneous classification of the mechanisms responsible for the radio emission. This variety is consistent with the radio intermediate (e.g. Falcke et al. 1996; Yuan et al. 2008) values of R_X in SUBWAYS. Interestingly, the points straddle the line between resolved and unresolved compact sources (vertical dashed black line) for telescopes with arcsecond resolving powers (e.g. Baldi 2023). Sub-arcsecond resolution observations may reveal compact jet structures or unresolved winds (Baldi et al. 2015; Baldi 2023; Chen et al. 2024).

⁸ A two-sided Fisher exact test on the 2×2 contingency table $([6, 1], [4, 11])$ yields $p \approx 0.020$ (the association is marginally significant at the $\sim 2\%$ level)

5.2. Radio spectral characteristics

Using the present observations, spanning the 145 MHz – 6 GHz interval, we compare the SED slopes in the 145 MHz–1.5 GHz and 1.5–6 GHz ranges (see Table 4) plotting them in Fig. 6 (left, also called colour-colour plot). To further quantify these spectral behaviours, we also compute the spectral curvature (SPC), defined here as the difference between the 1.5 - 6 GHz and 145 MHz - 1.5 GHz spectral indices ($\alpha_{6000}^{1500} - \alpha_{1500}^{145}$; Col. 5 of Table 4). In the left panel of Fig. 6, horizontal and vertical lines at 0 and 0.5 define the region where flat spectra are, while we classify as steep slopes above 0.5 and as inverted those below 0 (e.g. Panessa et al. 2022). If the value of SPC is null, the spectrum can be fitted by a single power law across the entire available frequency range, and the points are located along the bisector. Those located below exhibit instead a high frequency curvature and a positive SPC, consistent with spectral ageing of optically thin plasma. The SEDs of the objects above the bisector flatten towards higher frequencies (negative SPC), suggesting a combination of steep and flat components. If the upper limits and uncertainties are properly considered, all but one of the unresolved targets (PG1402+261) fall in the region where the spectral slope is flat in both regimes, indicative of single or multiple self-absorbed components consistent with either a corona or self-absorbed jet. In contrast, the resolved ones are all either steep or curved. This trend, coupled with the considerations on the sizes of Sect. 5.1, and the UFO detection in six of the resolved targets, suggests that compact and unresolved ones tend to exhibit a flat spectrum, typical of nuclear dense regions, whilst, coherently with the elongation of extended targets, star-formation activity or an outflow must be responsible for a steep or curved spectrum. This can be further quantified with a KM survival analysis, which shows that the UFO subsample has a median SPC around 0.11, while it is -0.07 for the other targets. However, also in this case if a log-rank test is performed, the p-value $p \sim 0.15$ is insufficient to state whether the UFO subsample belongs to a different distribution.

5.3. SFR contribution to radio emission

First of all, we verify whether SF can be considered the main mechanism for the production of radio emission. We derive the SFR from the 1.4 GHz luminosity following Condon (1992), and taking care of extrapolating the 1.5 GHz luminosity to 1.4 GHz using the spectral indices α_{6000}^{1500} listed in Table 4. For the sources exhibiting multiple components we exclude the extranuclear ones, whose morphology clearly suggests an origin not at-

Fig. 6. Left: radio colour-colour plots with the 1.5 - 6 GHz versus 145 MHz - 1.5 GHz spectral slopes. The yellow dots are the resolved objects while the blue ones are the unresolved ones. Dots are substituted with stars for UFO hosts. Upper limits are plotted with an arrow. Right: Histogram showing the distribution of the spectral curvature, defined as $\alpha_{6000}^{1500} - \alpha_{1500}^{145}$, for the UFO (filled) and NO UFO subsamples (barred). The SEDs of the UFO subsample (almost coincident with the extended class) typically steepen at GHz frequencies, consistently with the observed larger median extension, supporting the hypothesis that nuclear outflows evolve into large-scale winds, resulting in elongated radio morphologies and radio SEDs dominated by extended optically thin emitting regions.

tributable to the AGN host galaxy. The results are in Table 5 (Col. 3).

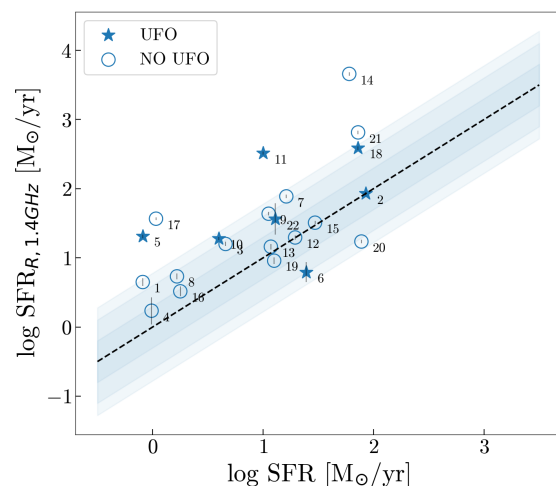

Fig. 7. $\log\text{SFR}$ derived from the radio luminosity following Condon (1992) against literature values of $\log\text{SFR}$ derived from IR diagnostics (Zhang et al. 2016). The blue shaded region represents the 1σ , 2σ , 3σ uncertainty on the relation. Some targets, labelled (*) in Table 5, are not studied in Zhang et al. (2016), thus their SFR has been computed from WISE flux densities according to the computations of Cluver et al. (2017). Numbers refer to single targets as in Table 5. Apart from five targets exceeding the 3σ uncertainty region, SUBWAYS AGNs follow the relation quite well. However, only PG1402+261 (15) and 2MASXJ1402+26 (13) exhibit SEDs consistent with being dominated by SF.

In the same table (Col. 4) we list the SFR values either based on near-infrared spectra and far-infrared photometry (Zhang et al. 2016), or derived from Wide-field Infrared Survey Explorer (WISE; Wright et al. 2010) flux densities (using Eq. 5 of Cluver et al. 2017). The latter are labelled with *.

Radio versus infrared (IR) values are plotted in Fig. 7. Five targets exceed the 3σ uncertainty region, implying that different processes beyond SF are required to explain their radio emission (e.g. White et al. 2017). In all other cases, the targets sit within 3σ of the relation. Despite this, either the radio emission extension, larger than the host galaxy as observed in optical images (see Appendix B), or the flat SED led us to exclude SF as main responsible for the radio emission. Only PG1402+261 and

Notes. Column (1): Target name. Column (2): Reference label as reported in the figures. Column (3): Logarithm of the star-formation rate derived from core radio luminosity (following Condon 1992). Column (4): Literature values for the logarithm of the star-formation rate derived from IR data in Zhang et al. (2016), or computed from WISE flux densities following Cluver et al. (2017) for objects marked with (*). Column (5): Radio luminosity at 5 GHz extrapolated from the measured 6 GHz (core) luminosity. Column (6): Radio loudness parameter R_X . Column (7): Logarithm of the wind kinetic luminosity from Paper III. Column (8): Logarithm of the radio luminosity expected from wind shocks according to Eq. 6, energy-conserving case. Column (9): Same as (8), momentum-conserving case. Column (10): Logarithm of the observed 6 GHz radio luminosity. The UFO subsample is shown before the horizontal line.

2MASXJ1402+26 are unresolved (see Appendix B) and exhibit values of α_{6000}^{1500} consistent with being dominated by an optically thin component ($\alpha \sim 0.6$) at GHz frequencies, making SF a viable source for the production of most radio emission. The overall observed trend suggests that some contribution from nuclear SF cannot be ruled out, though not dominating the emission, and consequently, the SED shape. This confirms the challenges in identifying the origin of radio emission in RQQ and emphasises the importance of employing complementary indicators.

5.4. X-ray - radio luminosity correlation

In works by Panessa et al. (2007), Laor & Behar (2008), and Panessa & Giroletti (2013), it has been observed that the 5 GHz radio luminosity and the 2-10 KeV X-ray one in RQ AGNs follow the empirical relation $L_R/L_X \sim 10^{-5.5}$ (Laor & Behar 2008), which is remarkably similar to the Güdel–Benz relation observed for coronally active stars (Guedel & Benz 1993). The latter is considered suggestive of a magnetically heated corona: magnetic reconnection releases energy, with a nearly constant fraction converted into heat (seen as X-ray emission) and particle acceleration (seen as synchrotron radio emission).

To test this scenario, we extrapolate the 6 GHz radio luminosities to 5 GHz, using as α_{6000}^{1500} those reported in Table 4. In Fig. 8, we plot the 5 GHz radio luminosity against the X-ray one derived in Paper I, and the empirical relation $L_R/L_X \sim 10^{-5.5}$ (dashed black line, with associated 1,2,3 σ uncertainties). For the three objects that exhibit extranuclear components, we consider only the luminosity of the nuclear one (A in Fig. 2).

First, it is possible to appreciate that the six objects exceeding the 3 σ uncertainty region are coherently catalogued as RL according to Terashima & Wilson (2003). Specifically, the fraction of UFO hosts deviating from the relation is 3/7, much larger than that of non-UFO hosts (3/15). This supports the interpretation that in AGNs with nuclear winds shocks from winds or small jets dominate radio emission at 5 GHz, and can significantly increase L_R relative to L_X (e.g. Zakamska et al. 2016; Mancuso et al. 2017; Richards et al. 2021; Baldi et al. 2022).

All the remaining objects closely follow the relation. However, as already mentioned in Sec. 5.1, current models indicate that corona-dominated emission, which is confined to sub-pc scales, should appear unresolved at arcsecond resolution and exhibit a self-absorbed radio spectrum at GHz frequencies, with spectral indices $\alpha_R \leq 0.2$ (Raginski & Laor 2016; del Palacio et al. 2025). Only PG0947+396 and PG1352+183 (surrounded by red diamonds in Fig. 8) match these predictions and are therefore good candidates for hosting corona-dominated radio emission.

In conclusion, similarly to the discussion related to SF in Sec. 5.3, although the Güdel–Benz relation seems to hold for RQQ almost independently on their spectral shape, a more detailed analysis using complementary diagnostics reveals that the origin of the radio emission cannot be uniquely attributed to coronal processes, highlighting the importance of a careful and multi-approach analysis.

In general, indeed, coronal emission can be more efficiently traced at millimeter wavelengths (100s GHz), where the millimeter excess eventually dominates and an unbiased and direct view of the corona is possible (Behar et al. 2015; Panessa et al.

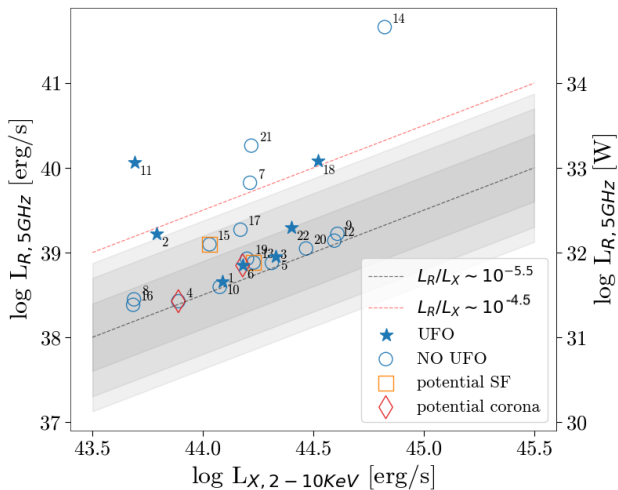

Fig. 8. Correlation between X-ray and radio luminosity. The dashed black line is the relationship found by Laor & Behar (2008) and the grey regions represent the 1σ , 2σ , 3σ uncertainty. The AGNs where the bulk of radio emission is due to SF are highlighted with orange squares while those where the emission is connected to the corona are surrounded by a red diamond. The dashed red line is the $R_X = -4.5$ traditional threshold between RL and RQ AGNs (Terashima & Wilson 2003). Six RL objects exceed the 3σ uncertainty region, but all other SUBWAYS targets follow the $L_R/L_X \sim 10^{-5.5}$ relation. PG0947+396 (6) and PG1352+183 (4) (red diamonds in the left panel), are unresolved and satisfy the expectations for a corona-dominated spectrum at GHz frequencies. The overall trend confirms that RQQ follow the Güdel–Benz relation almost independently on their radio spectral shape (e.g. Laor & Behar 2008; Panessa & Giroletti 2013).

2019; Kawamuro et al. 2022; Ricci et al. 2023; del Palacio et al. 2025). Therefore, our current results would be strengthened by a future analysis of the millimeter emission, which could provide proper evidence for a significant coronal contribution to the overall emission.

5.5. Expected radio emission from winds

Based on the results presented so far, while for two sources the radio emission could be explained with SF and for other two with the corona, for all the other objects all the diagnostics suggest the culprit should be an outflow, either in the form of wind or low-power jet. The observational signatures for the two mechanisms are very similar (i.e. steep GHz spectrum and extended emission), making it particularly complicated to disentangle (Wang et al. 2023) unless higher resolution observations are available.

Focusing on the UFO subsample, in this section we explore the interesting possibility that the observed radio emission originates from large-scale winds, which are the galactic-scale continuation of the X-ray nuclear outflows (King & Pounds 2015; Zubovas & Nardini 2020; Longinotti et al. 2023; Zanchettin et al. 2023). We attempt a connection between the kinetic luminosity of the nuclear winds to the properties of the radio emission, assuming that we observe radio synchrotron rising where the nuclear wind shocks the ISM.

As noted in Sect. 5.1, all UFO hosts except PG0947+396 are extended over tens of kpc and show steep SEDs, consistent with large-scale outflows and possibly supporting multi-phase wind models. In order to place more quantitative constraints, we follow Nims et al. (2015). Starting from the energy conserving wind

model of Faucher-Giguère & Quataert (2012), the authors propose an estimate for the expected radio luminosity at a frequency $\nu \geq \nu_{cool}$ (defined as the frequency after which νL_ν becomes flat)

$$L_{R,exp} = \nu L_\nu \approx 10^{-5} \xi_{-2} L_{AGN} \left(\frac{L_{k,o}}{0.05 L_{AGN}} \right) \text{erg/s}, \quad (6)$$

where ξ_{-2} is the energy conversion efficiency in units of 10^{-2} , L_{AGN} the AGN bolometric luminosity, and $L_{k,o}$ the kinetic luminosity of the radio wind. Under energy-conserving assumptions, we obtain $L_{R,exp}$ substituting $L_{k,o}$ with the value of the X-ray wind ($L_{k,i}$) derived for the SUBWAYS UFO subsample (Paper III). In Col. 9 of Table 5 we report for each UFO host the 5% efficiency estimates, with symmetric uncertainty computed as the distance from the 1% and 10% efficiency values, which is a reasonable efficiency range reported in the literature (e.g. Zubovas & King 2012; King & Pounds 2015; Zubovas & Nardini 2020). In Fig. 9 the blue stars represent the comparison between such values and the observed 6 GHz radio luminosity for the UFO subsample (computed on the whole extension of the targets). However, it is unlikely for the winds to maintain the same kinetic luminosity from UFO scales to kpc ones, where some energy dissipation should occur. For this reason, the blue stars should be interpreted as upper limits.

In order to find lower limits as well, we also consider the momentum-conserving scenario (following, e.g. Faucher-Giguère & Quataert 2012 and Zubovas & King 2012). In this case, the kinetic luminosity of the radio outflow $L_{k,o}$ differs from $L_{k,i}$ and can be estimated by comparing the momentum rate of the inner and outer wind: $\dot{P}_i = \dot{P}_o$. We get $L_{k,o} = L_{k,i} \cdot (v_o/v_i)$. The ratio between the typical velocity of a large-scale wind (ionised, HI or cold molecular) of $\sim 500 - 2000$ km/s (Zakamska & Greene 2014; Morganti et al. 2016; Fiore et al. 2017; Bischetti et al. 2019) and that of a UFO ($0.1 - 0.25c$ Chartas et al. 2002; Tombesi et al. 2012; Paper I) is around 0.01. Therefore, the radio wind roughly preserves only 1% of the nuclear wind power. The results are reported in Col. 9 of Table 5 and are plotted as red stars in Fig. 9.

The observed radio luminosity of our sample is included between the upper and lower limits, coherently with recent observations of multi-phase outflows on single sources (e.g. Tozzi et al. 2021; Bonanomi et al. 2023; Zanchettin et al. 2023; Longinotti et al. 2023, Baldini et al. 2024) that suggest reality actually lies in between the two limiting cases. Therefore, our result is consistent with radio emission being dominated by outflows. In particular, in terms of radio and X-ray properties, our UFO hosts share interesting similarities with IRAS17020+4544 (Longinotti et al. 2023) and NGC 2992 (Zanchettin et al. 2023), both hosting a multi-phase outflow. Moreover, the work by Villar-Martín et al. (2017) on 2MASXJ1653+23, strongly supports an outflow-related scenario.

Following the same procedure described above, we use the L_k values derived in Paper III for the local RQ AGNs belonging to Tombesi et al. (2010) sample to compute the expected radio luminosity. The observed radio luminosity of this set of AGNs is the result of extrapolations based on NASA/IPAC Extragalactic Database (NED) archival data⁹. In Fig. 9 we plot the upper limits as light grey diamonds and the lower limits as dark grey ones. Once again, with the exception of two cases, the one-to-one line is encompassed by the two threshold values, thus, a reasoning similar to that used for our sample applies here. With an orange triangle, we represent the median values for the sample of 568

⁹ <https://ned.ipac.caltech.edu>

Fig. 9. Expected radio luminosity versus observed one at 6 GHz for the SUBWAYS UFO subsample (M23, blue and red stars) and the comparison samples from Tombesi et al. (2010, T10, grey diamonds) and Zakamska & Greene (2014, Z14, orange empty triangle). For the latter only the median values are plotted. $L_{R,exp}$ is computed as from Eq. 6 with L_k from Paper III in both the energy-conserving (blue stars and light grey diamonds) and momentum-conserving (red stars and dark grey diamonds) scenario. The observed radio luminosity of our sample is included between upper and lower limits and is coherent with recent observations of multi-phase outflows (e.g. Zanchettin et al. 2023; Longinotti et al. 2023). The hypothesis of outflow-driven radio emission is further supported by the extended radio morphology and the steep radio spectral indices of UFO hosts.

luminous obscured QSO studied by Zakamska & Greene (2014, Z14). The authors derive L_k through a detailed analysis of gas kinematics and not from the UFO parameters, thus substituting its value in Eq. 6 we get a direct estimate of how much kinetic energy is converted into radiation.

In general, further modelling is needed to fully explain the complex interplay between the outflow and the ISM. We note that large-scale ($\sim kpc$) radio outflows develop on $\sim Myr$ timescales, much longer than the typical lifetimes of nuclear UFOs (Zubovas & King 2012; King & Pounds 2015; Zubovas & Nardini 2020). This mismatch implies that, if the radio outflow represents the large-scale extension of a nuclear wind, it is more likely associated with a past episode of nuclear activity of comparable intensity, rather than with the currently observed UFO. Alternatively, the observed coexistence of the two outflows may simply reflect physical conditions that favour the production of both phenomena.

To conclude, the above exercise shows that the bulk of radio emission in UFO hosts is consistent with being driven by an evolution of the nuclear wind. In addition we note that within our UFO subsample we detect steep-spectrum features extending beyond the stellar body of the galaxy, matching with outflow expectations. Although all previous observations fit well within a wind scenario, we stress that we cannot rule out the jet scenario based on this analysis. Higher resolution imaging and an estimate of the polarisation fraction may help to distinguish between the two (Wang et al. 2023; Chen et al. 2023; Meenakshi et al. 2024; Chen et al. 2024).

6. Summary and conclusions

We have analysed radio data of the AGNs in the SUBWAYS sample ($z=0.1-0.5$, $L_{bol} = 10^{44.9-46.3}$ erg/s) and investigated the origin of their radio emission, with a focus on radio-UFO connection, exploiting the availability of a unique combination of multi-band observations, as for RQQ the most likely origins considered are star-formation activity, AGN corona, wind, or jets. The radio proprietary data, simultaneously collected with JVLA at 1.5 and 6 GHz, have been complemented with archival images from LoTSS at 145 MHz, and from additional radio surveys (GMRT, RACS, FIRST, and VLASS) to cover a larger frequency range.

Below we summarise our most important results:

- The detection rate in the proprietary data is 100%. This decreases to 94% in LoTSS and even lower values in the other archival data, due to sensitivity limitations.

- The derived radio luminosities (with median values 23.28, 22.70, 22.43 W/Hz at 145 MHz, 1.5 GHz, and 6 GHz respectively; see Fig. 4), together with the radio loudness parameter computed by exploiting the available X-ray data, suggest that the sources can be classified as RQ or intermediate.

- The morphological classifications based on JVLA 6-GHz and LoTSS images are consistent, revealing twelve unresolved sources and ten resolved ones. For the unresolved sources, the upper limits of the emission extension range from ~ 1 kpc to < 10 kpc, therefore winds or low-power jets at sub-kpc and/or kpc scales, if present, could not be resolved. The resolved sources have linear sizes from ~ 10 kpc to 1000s kpc. One source, PG1425+267, is a Giant Radio QSO, extending for more than 1000 kpc (Fig. 2). This previously unidentified object is a serendipitous discovery of this work, which may be worth a detailed investigation in the future (see also Fig. 5).

- The radio SEDs, the radio colour-colour plots, and the spectral curvature (Fig. 4, left and middle) highlight a variety of spectral shapes, from simple power-laws, suggestive of an optically thin emitting plasma, to inverted and broken spectra, indicating the presence of an optically thick component dominating either at lower or higher frequencies (see Fig. 6). This is a hint of different mechanisms at the origin of the radio emission.

- Interestingly, six out of the seven UFO hosts show extended radio emission with steep spectra, consistent with outflowing optically thin plasma. While more robust conclusions require larger statistics and in-depth analysis, this may hint at a connection between the two phases, or simply reflect a more suitable environment for producing both phenomena.

- For all sources, we tested whether the observed radio emission is consistent with SF through the radio-IR correlation (Fig. 7). Similarly, we placed our targets in the $L_R - L_X$ plane to verify their location with respect to the Güdel-Benz relation ($L_R/L_X \sim 10^{-5.5}$; Fig. 8).

Overall, by combining the information from the correlations with the spectral and morphological properties, we find that only in two sources the radio emission may be dominated by SF and in the other two by the corona. With the currently available data, a dominant radio emission mechanism can be identified in just four sources (18%), highlighting the difficulty of analysing radio emission in RQQs, and underscoring the importance of employing complementary diagnostics.

- For all the rest it is likely that an outflow, either in the form of wind or jet, is mainly responsible for the radio emission. In particular, for the seven QSO showing UFOs we computed both upper (energy-conserving) and lower (momentum-conserving) limits for the expected wind radio emission. The observed ra-

dio luminosities of our sample lie between the upper and lower predicted limits, suggesting that winds might be a viable mechanism for explaining radio emission (Fig. 9). However, because of the huge degeneracy between the observables, we do not exclude the compact jet scenario.

Future perspectives

To further explore and confirm the results presented in this work, it would be interesting to verify the presence and properties of outflows in other gas phases and test their relation to the observed radio outflows and UFO. As an example, a uniform analysis of the already available optical SDSS spectra would allow us to test whether or not outflows as traced by [OIII] are detected (e.g. Zakamska & Greene 2014).

Also higher resolution observations of unresolved objects could give stronger constraints on their linear sizes, while for the resolved ones with flux densities of the order of mJy (e.g. with JVLA A configuration, e-MERLIN, and VLBI), those may reveal collimated sub-kpc-scale structures, helping to distinguish jets from winds, as noted in Panessa & Giroletti (2013) and Patil et al. (2020). Furthermore, the nuclear radio emission, measured from sub-arcsecond resolution observations, is expected to better correlate with the X-ray one, further supporting the corona scenario in some cases (Chen et al. 2024). We stress that future observations at 100-300 GHz with ALMA will be of great importance for more robust estimates of the corona contribution, not only to investigate spectral shapes (because of the lower frequencies sampled by our data a flat spectrum may be hidden) but also correlated mm-X-ray variability.

Finally, both the Next Generation VLA (ngVLA) and Square Kilometer Array (SKA), offering sub-arcsecond resolution (down to mas with ngVLA) and unprecedented sensitivities, will open new avenues for studying compact objects, even at higher redshift, providing the ideal opportunity to extend this kind of radio analysis to larger samples of sources hosting UFOs.

Data availability

Data associated with this article, including supplementary figures (e.g. the full SEDs and radio images), are available in the Zenodo repository Appendix B, under the Creative Commons License.

Notes. Column 1: target name. Column 2: central observing frequency. Column 3: restoring beam major axis, minor axis and position angle. Column 4: mean rms noise. Column 5: image dynamic range. Column 6: robust Briggs weighting. Column 7: minimum baseline. Below the reported value the baselines have been removed.

(*) Images obtained with WSClean.

([†]) Images that have been smoothed. The UFO subsample is shown before the horizontal line.
