Introduction Cognitive disorders are associated with a wide range of psychopathological syndromes and behavioral disorders, and suicidal manifestations in dementia are understudied nowadays.

Objectives To investigate clinical-psychopathological predictors of a suicidal behavior in patients with dementia.

Methodology Forty-four patients with dementia were examined: 23 patients with suicidal manifestations and 21 patients without them (control group). Clinical and psychometrical methods were used: Mini Mental State Examination (MMSE) scale; Assessment of Suicide Risk scale; Hamilton Rating Scale for Depression (HDRS), and statistical ones.

Results It was determined that male patients with dementia had suicidal behavioral manifestations more often than female patients (69.6%; P < 0.05). An average age of the patients was 69.88 ± 1.85 years with no significant difference between the main and control groups. The majority of the patients with dementia (52.3%) had suicidal manifestations. Real suicidal intentions were the most frequent (25%; P < 0.05); 20.5% of patients expressed passive thoughts (antivital sentences, fantasies, ideas concerning death); 2 patients (6.82%; P < 0.05) had suicidal attempts. Patients with suicidal tendencies in their clinical picture more often had hallucinatory syndrome (39.1%; P < 0.05); features of severe depression (35.04 ± 1.54 points; P < 0.01); a high level of suicidal risk (26.34 ± 1.68 points; P < 0.01); a severe cognitive deficit (MMSE score 0–10); and a significantly lower level of self-awareness of death (18.53 ± 0.72 points; P < 0.05) in comparison with the control group.

Conclusions A high suicide risk in dementia correlated with a level of depressive symptoms (r = 0.6), moderate and/or severe grades of dementia (r = 0.45), and a low level of self-awareness of death (r = 0.35).

Attemped suicide: Study of the phenomenon in a sample of patients in the province of Modena

Introduction Attempted suicide consists in a self-damaging non-fatal behaviour, with an explicit or implicit evidence of the intent to die. It has a multifactorial aetiology: presence of psychiatric disorder, particularly major depression and other non-psychiatric components, like a series of stressful events.

Aim To describe suicidal behavior among patients who attempted suicide.

Methods Cross-sectional study. Patients admitted to three hospitals in the Province of Modena (Italy) after having attempted suicide were enrolled. Observation time: August 2015–August 2016 (13 months). Descriptive statistics made with STATA 13.0.

Results A total of 187 subjects (female 65%) were enrolled in the period of time considered. Forty-one percent were aged 45–64; 43.7% had higher education; 50.4% were unemployed; 49.6% had regular income. Common means of attempted suicide were drugs (64%), weapons (11%), precipitation (10%), other (6%), choking (4%). Recent stressful events were reported by the 83.4% of respondents, namely: family conflicts (29%), economic problems (17%), personal health problems (11%), health problems affecting a family member (5%), emotional separation (9%), job loss (7%), other (22%), alcohol abuse (27%), substance abuse (4%). The main psychiatric diagnoses were: depressive disorder (56.67%), personality disorder (20%), psychotic disorder (6.67%), bipolar disorder (5.33%), behavioural disorders (2.67%), anxiety disorders (2%), dementia (1.33%).

Conclusions Findings of the present study are consistent with available literature and could help to identify “high risk” groups to plan future targeted programmes.
